Chapter 7

Complex Analysis and Conformal Mapping

The term “complex analysis” refers to the calculus of complex-valued functions $f(z)$ depending on a single complex variable $z$. To the novice, it may seem that this subject should merely be a simple reworking of standard real variable theory that you learned in first year calculus. However, this naïve first impression could not be further from the truth! Complex analysis is the culmination of a deep and far-ranging study of the fundamental notions of complex differentiation and integration, and has an elegance and beauty not found in the real domain. For instance, complex functions are necessarily \textit{analytic}, meaning that they can be represented by convergent power series, and hence are infinitely differentiable. Thus, difficulties with degree of smoothness, strange discontinuities, subtle convergence phenomena, and other pathological properties of real functions never arise in the complex regime.

The driving force behind many of the applications of complex analysis is the remarkable connection between complex functions and harmonic functions of two variables, a.k.a. solutions of the planar Laplace equation. To wit, the real and imaginary parts of any complex analytic function are automatically harmonic. In this manner, complex functions provide a rich lode of additional solutions to the two-dimensional Laplace equation, which can be exploited in a wide range of physical and mathematical applications. One of the most useful consequences stems from the elementary observation that the composition of two complex functions is also a complex function. We re-interpret this operation as a complex change of variables, producing a \textit{conformal mapping} that preserves angles. Conformal mappings can be effectively used for constructing solutions to the Laplace equation on complicated planar domains that appear in a wide range of physical problems, such as fluid flow, aerodynamics, thermomechanics, electrostatics, and elasticity.

In this chapter, we will develop the basic techniques and theorems of complex analysis that impinge on the solution to boundary value problems associated with the planar Laplace and Poisson equations. We refer the beginning reader to Appendix A for a quick review of the basics of complex numbers and complex arithmetic, and begin our exposition with the basics of complex functions and their differential calculus. We then proceed to develop the theory and applications of conformal mappings. The final section is devoted to complex integration and a few of its applications.

7.1. Complex Functions.

Our principal objects of study are complex-valued functions $f(z)$, depending on a single complex variable $z = x + iy$. In general, the function $f: \Omega \to \mathbb{C}$ will be defined on a subdomain, $z \in \Omega \subset \mathbb{C}$, of the complex plane.
Any complex function can be uniquely written as a complex combination

\[ f(z) = f(x + iy) = u(x, y) + iv(x, y), \]  

(7.1)

of two real functions, each depending on the two real variables \( x, y \): its real part \( u(x, y) = \text{Re}\, f(z) \) and its imaginary part \( v(x, y) = \text{Im}\, f(z) \). For example, according to the binomial formula, the monomial function \( f(z) = z^3 \) can be written as

\[ z^3 = (x + iy)^3 = (x^3 - 3xy^2) + i(3x^2y - y^3), \]

and so

\[ \text{Re}\, z^3 = x^3 - 3xy^2, \quad \text{Im}\, z^3 = 3x^2y - y^3. \]

Many of the well-known functions appearing in real-variable calculus — polynomials, rational functions, exponentials, trigonometric functions, logarithms, and many more — have natural complex extensions. For example, complex polynomials

\[ p(z) = a_n z^n + a_{n-1} z^{n-1} + \cdots + a_1 z + a_0 \]  

(7.2)

are complex linear combinations (meaning that the coefficients \( a_k \) are allowed to be complex numbers) of the basic monomial functions \( z^k = (x + iy)^k \). Similarly, we have already made use of complex exponentials such as

\[ e^z = e^{x+iy} = e^x \cos y + i e^x \sin y, \]

when solving differential equations and in Fourier analysis. Further examples will appear shortly.

There are several ways to motivate the link between harmonic functions \( u(x, y) \), meaning solutions of the two-dimensional Laplace equation

\[ \Delta u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0, \]  

(7.3)

and complex functions \( f(z) \). One natural starting point is to return to the d’Alembert solution (2.81) of the one-dimensional wave equation, which was based on the factorization

\[ \Box = \partial_t^2 - c^2 \partial_x^2 = (\partial_t - c \partial_x)(\partial_t + c \partial_x) \]

of the linear wave operator (2.67). The two-dimensional Laplace operator \( \Delta = \partial_x^2 + \partial_y^2 \) has essentially the same form, except for a “minor” change in sign\(^\dagger\). The Laplace operator admits a complex factorization,

\[ \Delta = \partial_x^2 + \partial_y^2 = (\partial_x - i\partial_y)(\partial_x + i\partial_y), \]

\(^\dagger\) However, this change in sign has serious ramifications for the analytical properties of (real) solutions. Section 4.3 discusses the profound differences between the elliptic Laplace equation and the hyperbolic wave equation.
into a product of first order differential operators, with complex “wave speeds” $c = \pm i$. Mimicking our previous solution formula (2.74) for the wave equation, we anticipate that the solutions to the Laplace equation (7.3) should be expressed in the form

$$u(x,y) = f(x + iy) + g(x - iy), \quad (7.4)$$

i.e., a linear combination of functions of the complex variable $z = x + iy$ and its complex conjugate $\overline{z} = x - iy$. The functions $f(x + iy)$ and $g(x - iy)$ formally satisfy the first order complex partial differential equations

$$\frac{\partial f}{\partial x} = -i \frac{\partial f}{\partial y}, \quad \frac{\partial g}{\partial x} = i \frac{\partial g}{\partial y}, \quad (7.5)$$

and hence (7.4) does indeed define a complex-valued solution to the Laplace equation.

In most applications, we are searching for a real solution to the Laplace equation, and so our complex d’Alembert-type formula (7.4) is not entirely satisfactory. As we know, a complex number $z = x + iy$ is real if and only if it equals its own conjugate, $z = \overline{z}$. Thus, the solution (7.4) will be real if and only if

$$f(x + iy) + g(x - iy) = u(x,y) = \overline{u(x,y)} = \overline{f(x + iy) + g(x - iy)}.$$

Now, the complex conjugation operation interchanges $x + iy$ and $x - iy$, and so we expect the first term $\overline{f(x + iy)}$ to be a function of $x - iy$, while the second term $\overline{g(x - iy)}$ will be a function of $x + iy$. Therefore†, to equate the two sides of this equation, we should require

$$g(x - iy) = \overline{f(x + iy)},$$

and so

$$u(x,y) = f(x + iy) + \overline{f(x + iy)} = 2 \text{Re} f(x + iy).$$

Dropping the inessential factor of 2, we conclude that a real solution to the two-dimensional Laplace equation can be written as the real part of a complex function. A more direct proof of the following key result will appear below.

**Proposition 7.1.** If $f(z)$ is a complex function, then its real part

$$u(x,y) = \text{Re} f(x + iy) \quad (7.6)$$

is a harmonic function.

The imaginary part of a complex function is also harmonic. This is because

$$\text{Im} f(z) = \text{Re} (-i f(z))$$

is the real part of the complex function

$$-i f(z) = -i [u(x,y) + i v(x,y)] = v(x,y) - i u(x,y).$$

† We are ignoring the fact that $f$ and $g$ are not quite uniquely determined since one can add and subtract a common constant. This does not affect the argument in any significant way.
Therefore, if \( f(z) \) is any complex function, we can write it as a complex combination

\[
f(z) = f(x + iy) = u(x, y) + iv(x, y),
\]

of two inter-related real harmonic functions: \( u(x, y) = \text{Re} \, f(z) \) and \( v(x, y) = \text{Im} \, f(z) \).

Before delving into the many remarkable properties of complex functions, let us look at some of the most basic examples. In each case, the reader can directly check that the harmonic functions provided by the real and imaginary parts of the complex function are indeed solutions to the Laplace equation.

**Examples of Complex Functions**

(a) **Harmonic Polynomials**: As noted above, any complex polynomial is a linear combination, as in (7.2), of the basic complex monomials

\[
z^n = (x + iy)^n = u_n(x, y) + iv_n(x, y).
\]

Similarly, the polynomial 

\[
\frac{1}{z} = \frac{x}{x^2 + y^2} - i \frac{y}{x^2 + y^2}
\]

is a harmonic function. Its real and imaginary parts are graphed in Figure 7.1. Note that these functions have an interesting singularity at the origin \( x = y = 0 \), but are harmonic everywhere else.
A slightly more complicated example is the function
\[ f(z) = \frac{z - 1}{z + 1}. \] (7.10)
To write out (7.10) in real form, we multiply and divide by the complex conjugate of the denominator, leading to
\[ f(z) = \frac{z - 1}{z + 1} = \frac{(z - 1)(\overline{z} + 1)}{(z + 1)(\overline{z} + 1)} = \frac{|z|^2 + z - \overline{z} - 1}{|z + 1|^2} = \frac{x^2 + y^2 - 1}{(x + 1)^2 + y^2} + i \frac{2y}{(x + 1)^2 + y^2}. \] (7.11)
Again, the real and imaginary parts are both harmonic functions away from the singularity \( x = -1, \ y = 0 \). Incidentally, the preceding manipulation can always be used to find the real and imaginary parts of general rational functions.

(c) Complex Exponentials: Euler’s formula
\[ e^z = e^x \cos y + i e^x \sin y \] (7.12)
for the complex exponential yields two important harmonic functions: \( e^x \cos y \) and \( e^x \sin y \), which are graphed in Figure 7.2. More generally, writing out \( e^{cz} \) for a complex constant \( c = a + i b \) produces the complex exponential function
\[ e^{cz} = e^{ax-by} \cos(bx + ay) + i e^{ax-by} \sin(bx + ay), \] (7.13)
whose real and imaginary parts are harmonic functions for arbitrary \( a, b \in \mathbb{R} \). Some of these were found by applying the separation of variables method in Cartesian coordinates.

(d) Complex Trigonometric Functions: The complex trigonometric functions are defined in terms of the complex exponential by adapting our earlier formulae (3.60):
\[ \cos z = \frac{e^{iz} + e^{-iz}}{2} = \cos x \cosh y - i \sin x \sinh y, \] (7.14)
\[ \sin z = \frac{e^{iz} - e^{-iz}}{2i} = \sin x \cosh y + i \cos x \sinh y. \]
The resulting harmonic functions are products of trigonometric and hyperbolic functions, and can all be written as linear combinations of the harmonic functions (7.13) derived from the complex exponential. Note that when \( z = x \) is real, so \( y = 0 \), these functions reduce to the usual real trigonometric functions \( \cos x \) and \( \sin x \).

(e) **Complex Logarithm:** In a similar fashion, the complex logarithm \( \log z \) is a complex extension of the usual real natural (i.e., base \( e \)) logarithm. In terms of polar coordinates \( z = r e^{i\theta} \), the complex logarithm has the form

\[
\log z = \log(r e^{i\theta}) = \log r + \log e^{i\theta} = \log r + i\theta. \tag{7.15}
\]

Thus, the logarithm of a complex number has real part

\[
\text{Re} (\log z) = \log r = \log |z| = \frac{1}{2} \log(x^2 + y^2),
\]

which is a well-defined harmonic function on all of \( \mathbb{R}^2 \) save for a logarithmic singularity at the origin \( x = y = 0 \). It is, up to multiple, the logarithmic potential (6.104) corresponding to a delta function forcing concentrated at the origin — which played a key role in our construction of the Green’s function for the Poisson equation.

The imaginary part

\[
\text{Im} (\log z) = \theta = \text{ph} z
\]

of the complex logarithm is the phase (or argument) of \( z \), also not defined at the origin \( x = y = 0 \). Moreover, the phase is a multiply-valued harmonic function elsewhere, since it is only specified up to integer multiples of \( 2\pi \). Each nonzero complex number \( z \neq 0 \) has an infinite number of possible values for its phase, and hence an infinite number of possible complex logarithms \( \log z \), differing from each other by an integer multiple of \( 2\pi i \), which reflects the fact that \( e^{2\pi i} = 1 \). In particular, if \( z = x > 0 \) is real and positive, then \( \log z = \log x \) agrees with the real logarithm, provided we choose \( \text{ph} x = 0 \). Alternative choices append some integer multiple of \( 2\pi i \), and so ordinary real, positive numbers \( x > 0 \)
also have complex logarithms! On the other hand, if \( z = x < 0 \) is real and negative, then \( \log z = \log |x| + (2k + 1) \pi i \) is complex no matter which value of \( \text{ph} z \) is chosen. (This explains why one avoids defining the logarithm of a negative number in first year calculus!)

Furthermore, as the point \( z \) circles once around the origin in a counter-clockwise direction, \( \text{Im} \log z = \text{ph} z = \theta \) increases by \( 2\pi \). Thus, the graph of \( \text{ph} z \) can be likened to a parking ramp with infinitely many levels, spiraling ever upwards as one circumambulates the origin; Figure 7.3 attempts to sketch it. At the origin, the complex logarithm exhibits a type of singularity known as a logarithmic branch point, the “branches” referring to the infinite number of possible values that can be assigned to \( \log z \) at any nonzero point.

(\( f \)) Roots and Fractional Powers: A similar branching phenomenon occurs with the fractional powers and roots of complex numbers. The simplest case is the square root function \( \sqrt{z} \). Every nonzero complex number \( z \neq 0 \) has two different possible square roots: \( \sqrt{z} \) and \(-\sqrt{z}\). Writing \( z = re^{i\theta} \) in polar coordinates, we find that

\[
\sqrt{z} = \sqrt{re^{i\theta}} = \sqrt{r} e^{i\theta/2} = \sqrt{r} \left( \cos \frac{\theta}{2} + i \sin \frac{\theta}{2} \right),
\]

i.e., we take the square root of the modulus and halve the phase:

\[
|\sqrt{z}| = |z| = \sqrt{r}, \quad \text{ph} \sqrt{z} = \frac{1}{2} \text{ph} z = \frac{1}{2} \theta.
\]

Since \( \theta = \text{ph} z \) is only defined up to an integer multiple of \( 2\pi \), the angle \( \frac{1}{2} \theta \) is only defined up to an integer multiple of \( \pi \). The even and odd multiples account for the two possible values of the square root.

In this case, if we start at some \( z \neq 0 \) and circle once around the origin, we increase \( \text{ph} z \) by \( 2\pi \), but \( \text{ph} \sqrt{z} \) only increases by \( \pi \). Thus, at the end of our circuit, we arrive at the other square root \(-\sqrt{z}\). Circling the origin again increases \( \text{ph} z \) by a further \( 2\pi \), and hence brings us back to the original square root \( \sqrt{z} \). Therefore, the graph of the multiply-valued square root function will look like a weirdly interconnected parking ramp with only two
levels, as sketched in Figure 7.4. The origin represents a branch point of order 2 for the square root function.

The preceding list of elementary examples is far from exhaustive. Lack of space will preclude us from studying the remarkable properties of complex versions of the gamma function, Airy functions, Bessel functions, and Legendre functions that appear later in the text, as well as the Riemann zeta function (3.58), elliptic functions, modular functions, and many, many other important and fascinating functions arising in complex analysis and its manifold applications. The interested reader is referred to [3, 137, 146].

7.2. Complex Differentiation.

The bedrock of complex function theory is the notion of the complex derivative. Complex differentiation is defined in the same manner as the usual calculus limit definition of the derivative of a real function. Yet, despite a superficial similarity, complex differentiation is a profoundly different theory, displaying an elegance and depth not shared by its real progenitor.

Definition 7.2. A complex function \( f(z) \) is differentiable at a point \( z \in \mathbb{C} \) if and only if the following limit exists:

\[
f'(z) = \lim_{w \to z} \frac{f(w) - f(z)}{w - z}.
\]

The key feature of this definition is that the limiting value \( f'(z) \) of the difference quotient must be independent of how \( w \) converges to \( z \). On the real line, there are only two directions to approach a limiting point — either from the left or from the right. These lead to the concepts of left- and right-handed derivatives and their equality is required for the existence of the usual derivative of a real function. In the complex plane, there are an infinite variety of directions to approach the point \( z \), and the definition requires that all of these “directional derivatives” must agree. This requirement imposes severe restrictions on complex derivatives, and is the source of their remarkable properties.

To analyze the basic definition, let us first see what happens when we approach \( z \) along the two simplest directions — horizontal and vertical. If we set

\[
w = z + h = (x + h) + iy,
\]

where \( h \) is real,

then \( w \to z \) along a horizontal line as \( h \to 0 \), as sketched in Figure 7.5. If we write out

\[
f(z) = u(x, y) + iv(x, y)
\]
in terms of its real and imaginary parts, then we must have

\[
f'(z) = \lim_{h \to 0} \frac{f(z + h) - f(z)}{h} = \lim_{h \to 0} \frac{f(x + h + iy) - f(x + iy)}{h}
\]

\[
= \lim_{h \to 0} \left[ \frac{u(x + h, y) - u(x, y)}{h} + i \frac{v(x + h, y) - v(x, y)}{h} \right] = \frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x} = \frac{\partial f}{\partial x},
\]
which follows from the usual definition of the (real) partial derivative. On the other hand, if we set
\[ w = z + i k = x + i (y + k), \quad \text{where } k \text{ is real}, \]
then \( w \to z \) along a vertical line as \( k \to 0 \). Therefore, we must also have
\[
    f'(z) = \lim_{k \to 0} \frac{f(z + i k) - f(z)}{i k} = \lim_{k \to 0} \left[ -i \frac{f(x + i(y + k)) - f(x + i y)}{k} \right]
    = \lim_{h \to 0} \left[ v(x, y + k) - v(x, y) \right] - i \left[ \frac{u(x, y + k) - u(x, y)}{k} \right]
    = \frac{\partial v}{\partial y} - i \frac{\partial u}{\partial y} = -i \frac{\partial f}{\partial y}.
\]

When we equate the real and imaginary parts of these two distinct formulae for the complex derivative \( f'(z) \), we discover that the real and imaginary components of \( f(z) \) must satisfy a certain homogeneous linear system of partial differential equations, named after Augustin–Louis Cauchy\(^\dagger\) and Bernhard Riemann\(^\ddagger\), two of the founders of modern complex analysis.

**Theorem 7.3.** A complex function \( f(z) = u(x, y) + i v(x, y) \) depending on \( z = x + i y \) has a complex derivative \( f'(z) \) if and only if its real and imaginary parts are continuously differentiable and satisfy the Cauchy–Riemann equations
\[
    \frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}.
\] (7.18)

In this case, the complex derivative of \( f(z) \) is equal to any of the following expressions:
\[
    f'(z) = \frac{\partial f}{\partial x} + i \frac{\partial f}{\partial y} = \frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x} = -i \frac{\partial f}{\partial y} = \frac{\partial v}{\partial y} - i \frac{\partial u}{\partial y}.
\] (7.19)

\(^\dagger\) Cauchy also played an essential role in establishing the mathematics of elasticity and materials science.

\(^\ddagger\) In addition to his contributions to complex analysis, partial differential equations and number theory, Riemann also was the inventor of the metric geometry of curved spaces, now known as Riemannian geometry, which turned out to be absolutely essential for Einstein’s theory of general relativity some 70 years later!
The proof of the converse — that any function whose real and imaginary components satisfy the Cauchy–Riemann equations is differentiable — will be omitted, but can be found in any basic text on complex analysis, e.g., [3, 65, 118].

Remark: It is worth pointing out that equation (7.19) tells us that $f$ satisfies $\frac{\partial f}{\partial x} = -i \frac{\partial f}{\partial y}$, which, reassuringly, agrees with the first equation in (7.5).

Example 7.4. Consider the elementary function

$$z^3 = (x^3 - 3x y^2) + i (3x^2 y - y^3).$$

Its real part $u = x^3 - 3x y^2$ and imaginary part $v = 3x^2 y - y^3$ satisfy the Cauchy–Riemann equations (7.18), since

$$\frac{\partial u}{\partial x} = 3x^2 - 3y^2 = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -6xy = -\frac{\partial v}{\partial x}.$$

Theorem 7.3 implies that $f(z) = z^3$ is complex differentiable. Not surprisingly, its derivative turns out to be

$$f'(z) = \frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x} = \frac{\partial v}{\partial y} - i \frac{\partial u}{\partial y} = (3x^2 - 3y^2) + i (6xy) = 3z^2.$$

Fortunately, the complex derivative obeys all of the usual rules that you learned in real-variable calculus. For example,

$$\frac{d}{dz} z^n = n z^{n-1}, \quad \frac{d}{dz} e^{cz} = c e^{cz}, \quad \frac{d}{dz} \log z = \frac{1}{z},$$

and so on. The power $n$ can be non-integral — or even, in view of the identity $z^n = e^{n \log z}$, complex, while $c$ is any complex constant. The exponential formulae (7.14) for the complex trigonometric functions implies that they also satisfy the standard rules

$$\frac{d}{dz} \cos z = -\sin z, \quad \frac{d}{dz} \sin z = \cos z.$$ 

The formulae for differentiating sums, products, ratios, inverses, and compositions of complex functions are all identical to their real counterparts, with similar proofs. Thus, thankfully, you don’t need to learn any new rules for performing complex differentiation!

Remark: There are many examples of seemingly reasonable functions which do not have a complex derivative. The simplest is the complex conjugate function

$$f(z) = \bar{z} = x - iy.$$

Its real and imaginary parts do not satisfy the Cauchy–Riemann equations, and hence $\bar{z}$ does not have a complex derivative. More generally, any function $f(z, \bar{z})$ that explicitly depends on the complex conjugate variable $\bar{z}$ is not complex-differentiable.
Power Series and Analyticity

A remarkable feature of complex differentiation is that the existence of one complex derivative automatically implies the existence of infinitely many! All complex functions \( f(z) \) are infinitely differentiable and, in fact, analytic where defined. The reason for this surprising and profound fact will, however, not become evident until we learn the basics of complex integration in Section 7.6. In this section, we shall take analyticity as a given, and investigate some of its principal consequences.

Definition 7.5. A complex function \( f(z) \) is called analytic at a point \( z_0 \in \mathbb{C} \) if it has a power series expansion

\[
f(z) = a_0 + a_1(z-z_0) + a_2(z-z_0)^2 + a_3(z-z_0)^3 + \cdots = \sum_{n=0}^{\infty} a_n (z-z_0)^n, \tag{7.22}
\]

which converges for all \( z \) sufficiently close to \( z_0 \).

Typically, the standard ratio or root tests for convergence of (real) series that you learned in ordinary calculus, [7, 129], can be applied to determine where a given (complex) power series converges. We note that if \( f(z) \) and \( g(z) \) are analytic at a point \( z_0 \), so is their sum \( f(z) + g(z) \), product \( f(z)g(z) \) and, provided \( g(z_0) \neq 0 \), ratio \( f(z)/g(z) \).

Example 7.6. All of the real power series found in elementary calculus carry over to the complex versions of the functions. For example,

\[
e^z = 1 + z + \frac{1}{2}z^2 + \frac{1}{6}z^3 + \cdots = \sum_{n=0}^{\infty} \frac{z^n}{n!} \tag{7.23}
\]

is the power series for the exponential function based at \( z_0 = 0 \). A straightforward application of the ratio test proves that the series converges for all \( z \). On the other hand, the power series

\[
\frac{1}{z^2+1} = 1 - z^2 + z^4 - z^6 + \cdots = \sum_{k=0}^{\infty} (-1)^k z^{2k}, \tag{7.24}
\]

converges inside the unit disk, where \( |z| < 1 \), and diverges outside, where \( |z| > 1 \). Again, convergence is established through the ratio test. The ratio test is inconclusive when \( |z| = 1 \), and we shall leave the more delicate question of precisely where on the unit disk this complex series converges to a more advanced treatment, e.g., [3].

In general, there are three possible options for the domain of convergence of a complex power series (7.22):

(a) The series converges for all \( z \).

(b) The series converges inside a disk \( |z-z_0| < \rho \) of radius \( \rho > 0 \) centered at \( z_0 \) and diverges for all \( |z-z_0| > \rho \) outside the disk. The series may converge at some (but not all) of the points on the boundary of the disk where \( |z-z_0| = \rho \).

(c) The series only converges, trivially, at \( z = z_0 \).

The number \( \rho \) is known as the radius of convergence of the series. In case (a), we say \( \rho = \infty \), while in case (c), \( \rho = 0 \), and the series does not represent an analytic function.
An example that has $\rho = 0$ is the power series $\sum n! z^n$. In the intermediate case (b), determining precisely where on the boundary of the convergence disk the power series converges is quite delicate, and will not be pursued here. The proof of this result is delegated to Exercise 6; see also [3, 65, 118] for further details.

Remarkably, the radius of convergence for the power series of a known analytic function $f(z)$ can be determined by inspection, without recourse to any fancy convergence tests! Namely, $\rho$ is equal to the distance from $z_0$ to the nearest singularity of $f(z)$, meaning a point where the function fails to be analytic. In particular, the radius of convergence $\rho = \infty$ if and only if $f(z)$ is analytic for all $z$, with no singularities; examples include $e^z$, $\cos z$, and $\sin z$. On the other hand, the rational function

$$f(z) = \frac{1}{z^2 + 1} = \frac{1}{(z + i)(z - i)}$$

has singularities at $z = \pm i$, and so its power series (7.24) has radius of convergence $\rho = 1$, which is the distance from $z_0 = 0$ to the singularities. Thus, the extension of the theory of power series to the complex plane serves to explain the apparent mystery of why, as a real function, $(1 + x^2)^{-1}$ is well-defined and analytic for all real $x$, but its power series only converges on the interval $(-1, 1)$. It is the complex singularities that prevent its convergence when $|x| > 1$. If we expand $(z^2 + 1)^{-1}$ in a power series at some other point, say $z_0 = 1 + 2i$, then we need to determine which singularity is closest. We compute $|i - z_0| = |-1 - i| = \sqrt{2}$, while $| - i - z_0| = |-1 - 3i| = \sqrt{10}$, and so the radius of convergence $\rho = \sqrt{2}$ is the smaller. Thus we can determine the radius of convergence without any explicit formula for its (rather complicated) Taylor expansion at $z_0 = 1 + 2i$.

There are, in fact, only three possible types of singularities of a complex function $f(z)$:

- **Pole.** A singular point $z = z_0$ is called a *pole of order* $n > 0$ if and only if

  $$f(z) = \frac{h(z)}{(z - z_0)^n}, \hspace{1cm} (7.25)$$

  where $h(z)$ is analytic at $z = z_0$ and $h(z_0) \neq 0$. The simplest example of such a function is $f(z) = a(z - z_0)^{-n}$ for $a \neq 0$ a complex constant.

- **Branch point.** We have already encountered the two basic types: *algebraic branch points*, such as the function $\sqrt[2]{z}$ at $z_0 = 0$, and *logarithmic branch points* such as log $z$ at $z_0 = 0$. The *degree* of the branch point is $n$ in the first case and $\infty$ in the second.

- **Essential singularity.** By definition, a singularity is *essential* if it is not a pole or a branch point. Essential singularities are considerably more complicated than poles and branch points. The quintessential example is the essential singularity of the function $e^{1/z}$ at $z_0 = 0$.

**Example 7.7.** The complex function

$$f(z) = \frac{e^z}{z^3 - z^2 - 5z - 3} = \frac{e^z}{(z - 3)(z + 1)^2}$$
is analytic everywhere except for singularities at the points $z = 3$ and $z = -1$, where its
denominator vanishes. Since

$$f(z) = \frac{h_1(z)}{z-3}, \quad \text{where} \quad h_1(z) = \frac{e^z}{(z+1)^2}$$

is analytic at $z = 3$ and $h_1(3) = \frac{1}{16} e^3 \neq 0$, we conclude that $z = 3$ is a simple (order 1)
pole. Similarly,

$$f(z) = \frac{h_2(z)}{(z+1)^2}, \quad \text{where} \quad h_2(z) = \frac{e^z}{z-3}$$

is analytic at $z = -1$ with $h_2(-1) = -\frac{1}{4} e^{-1} \neq 0$, we see that the point $z = -1$ is a double
(order 2) pole.

A complicated complex function can have a variety of singularities. For example, the
function

$$f(z) = \frac{\sqrt[3]{z+2} e^{-1/2z^2}}{z^2 + 1}$$

has simple poles at $z = \pm i$, a branch point of degree 3 at $z = -2$, and an essential
singularity at $z = 1$.

As in the real case, and unlike Fourier series, convergent power series can always be
repeatedly term-wise differentiated. Therefore, given the convergent series (7.22), we have
the corresponding series

$$f'(z) = a_1 + 2a_2(z-z_0) + 3a_3(z-z_0)^2 + 4a_4(z-z_0)^3 + \cdots$$

$$= \sum_{n=0}^{\infty} (n+1)a_{n+1}(z-z_0)^n,$$

$$f''(z) = 2a_2 + 6a_3(z-z_0) + 12a_4(z-z_0)^2 + 20a_5(z-z_0)^3 + \cdots$$

$$= \sum_{n=0}^{\infty} (n+1)(n+2)a_{n+2}(z-z_0)^n,$$

and so on, for its derivatives. In Exercise you are asked to prove that the differentiated
series all have the same radius of convergence as the original. As a consequence, we deduce
the following important result.

**Theorem 7.8.** Any analytic function is infinitely differentiable.

In particular, when we substitute $z = z_0$ into the successively differentiated series, we
discover that

$$a_0 = f(z_0), \quad a_1 = f'(z_0), \quad a_2 = \frac{1}{2} f''(z_0),$$

and, in general,

$$a_n = \frac{f^{(n)}(z)}{n!}.$$
Therefore, a convergent power series (7.22) is, inevitably, the usual *Taylor series*

\[
f(z) = \sum_{n=0}^{\infty} \frac{f^{(n)}(z_0)}{n!} (z - z_0)^n,
\]

for the function \(f(z)\) at the point \(z_0\).

Let us conclude this section by summarizing the fundamental theorem that characterizes complex functions. A complete, rigorous proof relies on complex integration theory, which is the topic of Section 7.6.

**Theorem 7.9.** Let \(\Omega \subset \mathbb{C}\) be an open set. The following properties are equivalent:

(a) The function \(f(z)\) has a continuous complex derivative \(f'(z)\) for all \(z \in \Omega\).

(b) The real and imaginary parts of \(f(z)\) have continuous partial derivatives and satisfy the Cauchy–Riemann equations (7.18) in \(\Omega\).

(c) The function \(f(z)\) is analytic for all \(z \in \Omega\), and so is infinitely differentiable and has a convergent power series expansion at each point \(z_0 \in \Omega\). The radius of convergence \(\rho\) is at least as large as the distance from \(z_0\) to the boundary \(\partial \Omega\), as in Figure 7.6.

From now on, we reserve the term *complex function* to signify one that satisfies the conditions of Theorem 7.9. Sometimes one of the equivalent adjectives “analytic” or “holomorphic”, is added for emphasis. From now on, all complex functions are assumed to be analytic everywhere on their domain of definition, except, possibly, at certain isolated singularities.

### 7.3. Harmonic Functions.

We began this chapter by motivating the analysis of complex functions through applications to the solution of the two-dimensional Laplace equation. Let us now formalize the precise relationship between the two subjects.

**Theorem 7.10.** If \(f(z) = u(x, y) + iv(x, y)\) is any complex analytic function, then its real and imaginary parts, \(u(x, y), v(x, y)\), are both harmonic functions.
Proof: Differentiating\(^†\) the Cauchy–Riemann equations (7.18), and invoking the equality of mixed partial derivatives, we find that
\[
\frac{\partial^2 u}{\partial x^2} = \frac{\partial}{\partial x} \left( \frac{\partial u}{\partial x} \right) = \frac{\partial}{\partial x} \left( \frac{\partial v}{\partial y} \right) = \frac{\partial^2 v}{\partial x \partial y} = \frac{\partial}{\partial y} \left( \frac{\partial v}{\partial x} \right) = \frac{\partial}{\partial y} \left( - \frac{\partial u}{\partial y} \right) = - \frac{\partial^2 u}{\partial y^2}.
\]
Therefore, \(u\) is a solution to the Laplace equation \(u_{xx} + u_{yy} = 0\). The proof for \(v\) is similar. Q.E.D.

Thus, every complex function gives rise to two harmonic functions. It is, of course, of interest to know whether we can invert this procedure. Given a harmonic function \(u(x,y)\), does there exist a harmonic function \(v(x,y)\) such that \(f = u + iv\) is a complex analytic function? If so, the harmonic function \(v(x,y)\) is known as a harmonic conjugate to \(u\). The harmonic conjugate is found by solving the Cauchy–Riemann equations
\[
\frac{\partial v}{\partial x} = - \frac{\partial u}{\partial y}, \quad \frac{\partial v}{\partial y} = \frac{\partial u}{\partial x}, \quad (7.30)
\]
which, for a prescribed function \(u(x,y)\), constitutes an inhomogeneous linear system of partial differential equations for \(v(x,y)\). As such, it is usually not hard to solve, as the following example illustrates.

Example 7.11. As the reader can verify, the harmonic polynomial
\[
u(x,y) = x^3 - 3x^2 y - 3xy^2 + y^3
\]
satisfies the Laplace equation everywhere. To find a harmonic conjugate, we solve the Cauchy–Riemann equations (7.30). First of all,
\[
\frac{\partial v}{\partial x} = - \frac{\partial u}{\partial y} = 3x^2 + 6xy - 3y^2,
\]
and hence, by direct integration with respect to \(x\),
\[
v(x,y) = x^3 + 3x^2 y - 3xy^2 + h(y),
\]
where \(h(y)\) — the “constant of integration” — is a function of \(y\) alone. To determine \(h\) we substitute our formula into the second Cauchy–Riemann equation:
\[
3x^2 - 6xy + h'(y) = \frac{\partial v}{\partial y} = \frac{\partial u}{\partial x} = 3x^2 - 6xy - 3y^2.
\]
Therefore, \(h'(y) = -3y^2\), and so \(h(y) = -y^3 + c\), where \(c\) is a real constant. We conclude that every harmonic conjugate to \(u(x,y)\) has the form
\[
v(x,y) = x^3 + 3x^2 y - 3xy^2 - y^3 + c.
\]
Note that the corresponding complex function
\[
u(x,y) + iv(x,y) = (x^3 - 3x^2 y - 3xy^2 + y^3) + i(x^3 + 3x^2 y - 3xy^2 - y^3 + c)
\]
\[
= (1 - i)z^3 + c
\]
turns out to be a complex cubic polynomial.

\(^†\) Theorem 7.9 allows us to differentiate \(u\) and \(v\) as often as desired.
Remark: On a connected domain \( \Omega \subset \mathbb{R}^2 \), all harmonic conjugates to a given function \( u(x, y) \) only differ by a constant: \( \tilde{v}(x, y) = v(x, y) + c \); see Exercise 1.

Although most harmonic functions have harmonic conjugates, unfortunately this is not always the case. Interestingly, the existence or non-existence of a harmonic conjugate can depend on the underlying topology of its domain of definition. If the domain is simply connected, and so contains no holes, then one can *always* find a harmonic conjugate. On non-simply connected domains, there may not exist a single-valued harmonic conjugate to serve as the imaginary part of a complex function \( f(z) \).

**Example 7.12.** The simplest example where the latter possibility occurs is the logarithmic potential
\[
u(x, y) = \log r = \frac{1}{2} \log(x^2 + y^2).
\]
This function is harmonic on the non-simply connected domain \( \Omega = \mathbb{C} \setminus \{0\} \), but is not the real part of any single-valued complex function. Indeed, according to (7.15), the logarithmic potential is the real part of the multiply-valued complex logarithm \( \log z \), and so its harmonic conjugate\(^\dagger\) is \( \text{ph} z = \theta \), which cannot be consistently and continuously defined on all of \( \Omega \). On the other hand, on any simply connected subdomain \( \tilde{\Omega} \subset \Omega \), one can select a continuous, single-valued branch of the angle \( \theta = \text{ph} z \), which is then a bona fide harmonic conjugate to \( \log r \) restricted to this subdomain.

The harmonic function
\[
u(x, y) = \frac{x}{x^2 + y^2}
\]
is also defined on the same non-simply connected domain \( \Omega = \mathbb{C} \setminus \{0\} \) with a singularity at \( x = y = 0 \). In this case, there is a single valued harmonic conjugate, namely
\[
v(x, y) = -\frac{y}{x^2 + y^2},
\]
which is defined on all of \( \Omega \). Indeed, according to (7.9), these functions define the real and imaginary parts of the complex function \( u + iv = 1/z \). Alternatively, one can directly check that they satisfy the Cauchy–Riemann equations (7.18).

Remark: On the “punctured” plane \( \Omega = \mathbb{C} \setminus \{0\} \), the logarithmic potential is, in a sense, the only obstruction to the existence of a harmonic conjugate. It can be shown, [74], that if \( u(x, y) \) is a harmonic function defined on a punctured disk \( \Omega_R = \{ 0 < |z| < R \} \), where \( 0 < R \leq \infty \), then there exists a constant \( c \) such that \( \tilde{u}(x, y) = u(x, y) - c \log \sqrt{x^2 + y^2} \) is also harmonic and possess a single-valued harmonic conjugate \( \tilde{v}(x, y) \). As a result, the function \( \tilde{f} = \tilde{u} + i \tilde{v} \) is analytic on all of \( \Omega_R \), and so our original function \( u(x, y) \) is the real part of the multiply-valued analytic function \( f(z) = \tilde{f}(z) + c \log z \). This fact will be of importance in our analysis of airfoils.

\(^\dagger\) We can, by the preceding remark, add in any constant to the harmonic conjugate, but this does not affect the subsequent argument.
Theorem 7.13. Every harmonic function \( u(x, y) \) defined on a simply connected domain \( \Omega \) is the real part of a complex valued function \( f(z) = u(x, y) + iv(x, y) \) which is defined for all \( z = x + iy \in \Omega \).

Proof: We first rewrite the Cauchy–Riemann equations (7.30) in vectorial form as an equation for the gradient of \( v \):

\[
\nabla v = \nabla^\perp u, \quad \text{where} \quad \nabla^\perp u = \left( -u_y, u_x \right)
\]

(7.31)
is the skew gradient of \( u \). As in (6.78), it is everywhere orthogonal to the gradient of \( u \) and of the same length:

\[
\nabla u \cdot \nabla v = 0, \quad \| \nabla u \| = \| \nabla^\perp u \|.
\]

Thus, we have established the important observation that the gradient of a harmonic function and that of its harmonic conjugate are mutually orthogonal vector fields having the same Euclidean lengths:

\[
\nabla u \cdot \nabla v \equiv 0, \quad \| \nabla u \| \equiv \| \nabla v \|.
\]

(7.32)

Now, given the harmonic function \( u \), our goal is to construct a solution \( v \) to the gradient equation (7.31). A well-known result from vector calculus states the vector field defined by \( \nabla^\perp u \) has a potential function \( v \) if and only if the corresponding line integral is independent of path, which means that

\[
0 = \oint_C \nabla v \cdot \mathbf{n} \, ds = \oint_C \nabla^\perp u \cdot \mathbf{n} \, ds = \oint_C \nabla u \cdot \mathbf{n} \, ds,
\]

(7.33)

for every closed curve \( C \subset \Omega \). Indeed, if this holds, then a potential function can be devised\(^\dagger\) by integrating the vector field:

\[
v(x, y) = \int_a^x \nabla v \cdot d\mathbf{x} = \int_a^x \nabla u \cdot \mathbf{n} \, ds.
\]

(7.34)

Here \( a \in \Omega \) is any fixed point, and, in view of path independence, the line integral can be taken over any curve that connects \( a \) to \( \mathbf{x} = (x, y) \).

If the domain \( \Omega \) is simply connected then every simple closed curve \( C \subset \Omega \) bounds a subdomain \( D \subset \Omega \) with \( C = \partial D \). Applying the divergence form of Green’s Theorem (6.80), we find

\[
\oint_C \nabla u \cdot \mathbf{n} \, ds = \iint_D \nabla \cdot \nabla u \, dx \, dy = \iint_D \Delta u \, dx \, dy = 0,
\]

because \( u \) is harmonic. Thus, we have proved\(^\ddagger\) the existence of a harmonic conjugate function — provided the underlying domain is simply connected.

\[Q.E.D.\]

\(\dagger\) This assumes that the domain \( \Omega \) is connected; if not, we merely apply the argument on each connected component.

\(\ddagger\) Technically, we have only verified path-independence (7.33) when \( C \) is a simple closed curve, but this suffices to establish it for arbitrary closed curves; see the proof of Proposition 7.50 for details.
Remark: As a consequence of (7.19) and the Cauchy–Riemann equations (7.30),

\[ f'(z) = \frac{\partial u}{\partial x} - i \frac{\partial u}{\partial y} = \frac{\partial v}{\partial y} + i \frac{\partial v}{\partial x}. \]  

(7.35)

Thus, the individual components of the gradients \( \nabla u \) and \( \nabla v \) appear as the real and imaginary parts of the complex derivative \( f'(z) \).

The orthogonality (7.31) of the gradient of a function and of its harmonic conjugate has the following important geometric consequence. Recall, [7, 129], that the gradient \( \nabla u \) of a function \( u(x, y) \) points in the normal direction to its level curves, that is, the sets \( \{ u(x, y) = c \} \) where it assumes a fixed constant value. Since \( \nabla v \) is orthogonal to \( \nabla u \), this must mean that \( \nabla v \) is tangent to the level curves of \( u \). Vice versa, \( \nabla v \) is normal to its level curves, and so \( \nabla u \) is tangent to the level curves of its harmonic conjugate \( v \). Since their tangent directions \( \nabla u \) and \( \nabla v \) are orthogonal, the level curves of the real and imaginary parts of a complex function form a mutually orthogonal system of plane curves — but with one key exception. If we are at a critical point, where \( \nabla u = 0 \), then \( \nabla v = \nabla^\perp u = 0 \), and the vectors do not define tangent directions. Therefore, the orthogonality of the level curves does not necessarily hold at critical points. It is worth pointing out that, in view of (7.35), the critical points of \( u \) are the same as those of \( v \) and also the same as the critical points of the corresponding complex function \( f(z) \), i.e., those points where its complex derivative vanishes: \( f'(z) = 0 \).

In Figure 7.7, we illustrate the preceding paragraph by plotting the level curves of the real and imaginary parts of the functions \( f(z) = z^2 \) and \( z^3 \). Note that, except at the origin, where the derivative vanishes, the level curves intersect everywhere at right angles.

Applications to Fluid Mechanics

Consider a planar steady state fluid flow, with velocity vector field

\[ \mathbf{v}(\mathbf{x}) = (u(x, y), v(x, y)) \quad \text{at the point} \quad \mathbf{x} = (x, y) \in \Omega. \]

Here \( \Omega \subset \mathbb{R}^2 \) is the domain occupied by the fluid, while the vector \( \mathbf{v}(\mathbf{x}) \) represents the instantaneous velocity of the fluid at the point \( \mathbf{x} \in \Omega \). Recall that the flow is incompressible.
if and only if it has vanishing divergence:
\[ \nabla \cdot \mathbf{v} = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0. \] (7.36)

Incompressibility means that the fluid volume does not change as it flows. Most liquids, including water, are, for all practical purposes, incompressible. On the other hand, the flow is \textit{irrotational} if and only if it has vanishing curl:
\[ \nabla \times \mathbf{v} = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = 0. \] (7.37)

Irrotational flows have no vorticity, and hence no circulation. A flow that is both incompressible and irrotational is known as an \textit{ideal fluid flow}. In many physical regimes, liquids (and, although less often, gases) behave as \textit{ideal fluids}.

Observe that the two constraints (7.36–37) are almost identical to the Cauchy–Riemann equations (7.18); the only difference is the change in sign in front of the derivatives of \( v \).

But this can be easily remedied by replacing \( v \) by its negative \(-v\). As a result, we establish a profound connection between ideal planar fluid flows and complex functions.

\textbf{Theorem 7.14.} The velocity vector field \( \mathbf{v} = (u(x,y), v(x,y)) \) induces an ideal fluid flow if and only if
\[ f(z) = u(x,y) - i v(x,y) \] (7.38)

is a complex analytic function of \( z = x + iy \).

Thus, the components \( u(x,y) \) and \(-v(x,y)\) of the velocity vector field for an ideal fluid flow are necessarily harmonic conjugates. The corresponding complex function (7.38) is, not surprisingly, known as the \textit{complex velocity} of the fluid flow. When using this result, \textit{do not forget} the minus sign that appears in front of the imaginary part of \( f(z) \).

Under the flow induced by the velocity vector field \( \mathbf{v} = (u(x,y), v(x,y)) \), the fluid particles follow the trajectories \( z(t) = x(t) + iy(t) \) obtained by integrating the system of ordinary differential equations
\[ \frac{dx}{dt} = u(x,y), \quad \frac{dy}{dt} = v(x,y). \] (7.39)

In view of the representation (7.38), we can rewrite the system in complex form
\[ \frac{dz}{dt} = f(z). \] (7.40)

In fluid mechanics, the curves parametrized by \( z(t) \) are known as the \textit{streamlines}. Each fluid particle’s motion \( z(t) \) is uniquely prescribed by its position \( z(t_0) = z_0 = x_0 + iy_0 \) at an initial time \( t_0 \). In particular, if the complex velocity vanishes, \( f(z_0) = 0 \), then the solution \( z(t) \equiv z_0 \) to (7.40) is constant, and hence \( z_0 \) is a \textit{stagnation point} of the flow. Our steady state assumption, which is reflected in the fact that the ordinary differential equations (7.39) are autonomous, i.e., there is no explicit \( t \) dependence, means that, although the fluid is in motion, the streamlines and stagnation point do not change over time. This is a consequence of the standard existence and uniqueness theorems for solutions to ordinary differential equations, \cite{23, 32, 62}.
Example 7.15. The simplest example is when the velocity is constant, corresponding to a uniform, steady flow. Consider first the case
\[ f(z) = 1, \]
which corresponds to the horizontal velocity vector field \( \mathbf{v} = (1, 0) \). The actual fluid flow is found by integrating the system
\[ \dot{z} = 1, \quad \text{or} \quad \dot{x} = 1, \quad \dot{y} = 0. \]
Thus, the solution \( z(t) = t + z_0 \) represents a uniform horizontal fluid motion whose streamlines are straight lines parallel to the real axis; see Figure 7.8.

Consider next a more general constant velocity
\[ f(z) = c = a + i b. \]
The fluid particles will solve the ordinary differential equation
\[ \dot{z} = \overline{c} = a - i b, \quad \text{so that} \quad z(t) = \overline{c} t + z_0. \]
The streamlines remain parallel straight lines, but now at an angle \( \theta = \text{ph} \overline{c} = - \text{ph} c \) with the horizontal. The fluid particles move along the streamlines at constant speed \( |\overline{c}| = |c| \).

The next simplest complex velocity function is
\[ f(z) = z = x + i y. \] (7.41)
The corresponding fluid flow is found by integrating the system
\[ \dot{z} = \overline{z}, \quad \text{or, in real form,} \quad \dot{x} = x, \quad \dot{y} = -y. \]
The origin \( x = y = 0 \) is a stagnation point. The trajectories of the nonstationary solutions
\[ z(t) = x_0 e^t + i y_0 e^{-t} \] (7.42)
are the hyperbolas \( xy = c \), along with the positive and negative coordinate semi-axes, as illustrated in Figure 7.8.
On the other hand, if we choose

\[ f(z) = -i z = y - i x, \]

then the flow is the solution to

\[ \dot{z} = i \bar{z}, \]

or, in real form,

\[ \dot{x} = y, \quad \dot{y} = x. \]

The solutions

\[ z(t) = (x_0 \cosh t + y_0 \sinh t) + i (x_0 \sinh t + y_0 \cosh t), \]

move along the hyperbolas (and rays) \( x^2 - y^2 = c^2 \). Observe that this flow can be obtained by rotating the preceding example by \( 45^\circ \).

In general, a solid object in a fluid flow is characterized by the no-flux condition that the fluid velocity \( \mathbf{v} \) is everywhere tangent to the boundary, and hence no fluid flows into or out of the object. As a result, the boundary will necessarily consist of streamlines and stagnation points of the idealized fluid flow. For example, the boundary of the upper right quadrant \( Q = \{ x > 0, y > 0 \} \subseteq \mathbb{C} \) consists of the positive \( x \) and \( y \) axes (along with the origin). Since these are streamlines of the flow with complex velocity (7.41), its restriction to \( Q \) represents an ideal flow past a \( 90^\circ \) interior corner, which is illustrated in Figure 7.9. The individual fluid particles move along hyperbolas as they flow past the corner.

Remark: We could also restrict this flow to the domain \( \Omega = \mathbb{C} \setminus \{ x < 0, y < 0 \} \) consisting of three quadrants, corresponding to a \( 90^\circ \) exterior corner. However, this flow is not as physically relevant since it has an unrealistic asymptotic behavior at large distances. See Exercise \textbullet for a more realistic flow around an exterior corner.

Now, suppose that the complex velocity \( f(z) \) admits a complex anti-derivative, i.e., a complex analytic function

\[ \chi(z) = \varphi(x, y) + i \psi(x, y) \]

that satisfies

\[ \frac{d\chi}{dz} = f(z). \]
Using formula (7.19) for the complex derivative,
\[
\frac{d\chi}{dz} = \frac{\partial \varphi}{\partial x} - i \frac{\partial \varphi}{\partial y} = u - i v,
\]
so \( \frac{\partial \varphi}{\partial x} = u, \frac{\partial \varphi}{\partial y} = v. \)

Thus, \( \nabla \varphi = v, \) and hence the real part \( \varphi(x,y) \) of the complex function \( \chi(z) \) defines a \textit{velocity potential} for the fluid flow. For this reason, the anti-derivative \( \chi(z) \) is known as a \textit{complex potential function} for the given fluid velocity field.

Since the complex potential is analytic, its real part — the potential function — is harmonic, and therefore satisfies the Laplace equation \( \Delta \varphi = 0. \) Conversely, any harmonic function can be viewed as the potential function for some fluid flow. The real fluid velocity is its gradient \( v = \nabla \varphi. \) The harmonic conjugate \( \psi(x,y) \) to the velocity potential also plays an important role, and, in fluid mechanics, is known as the \textit{stream function}. It also satisfies the Laplace equation \( \Delta \psi = 0, \) and the potential and stream function are related by the Cauchy–Riemann equations (7.18):
\[
\frac{\partial \varphi}{\partial x} = u = \frac{\partial \psi}{\partial y}, \quad \frac{\partial \varphi}{\partial y} = v = -\frac{\partial \psi}{\partial x}.
\]

The \textit{level sets} of the velocity potential, \( \{ \varphi(x,y) = c \}, \) where \( c \in \mathbb{R} \) is fixed, are known as \textit{equipotential curves}. The velocity vector \( v = \nabla \varphi \) points in the normal direction to the equipotentials. On the other hand, as we noted above, \( v = \nabla \varphi \) is tangent to the level curves \( \{ \psi(x,y) = d \} \) of its harmonic conjugate stream function. But \( v \) is the velocity field, and so tangent to the streamlines followed by the fluid particles. Thus, these two systems of curves must coincide, and we infer that the \textit{level curves of the stream function are the streamlines of the flow}, whence its name! Summarizing, for an ideal fluid flow, the equipotentials \( \{ \varphi = c \} \) and streamlines \( \{ \psi = d \} \) form mutually orthogonal systems of plane curves. The fluid velocity \( v = \nabla \varphi \) is tangent to the stream lines and normal to the equipotentials, whereas the gradient of the stream function \( \nabla \psi \) is tangent to the equipotentials and normal to the streamlines.

The discussion in the preceding paragraph implicitly relied on the fact that the velocity is nonzero, \( v = \nabla \varphi \neq 0, \) which means we are not at a stagnation point, where the fluid is not moving. While streamlines and equipotentials might begin or end at a stagnation point, there is no guarantee, and, indeed, in general it is not the case that they meet at mutually orthogonal directions there.

\textbf{Example 7.16.} The simplest example of a complex potential function is
\[
\chi(z) = z = x + i y.
\]

Thus, the velocity potential is \( \varphi(x,y) = x, \) while its harmonic conjugate stream function is \( \psi(x,y) = y. \) The complex derivative of the potential is the complex velocity,
\[
f(z) = \frac{d\chi}{dz} = 1,
\]
which corresponds to the uniform horizontal fluid motion considered first in Example 7.15. Note that the horizontal stream lines coincide with the level sets \( \{ y = d \} \) of the stream
function, whereas the equipotentials \( \{ x = c \} \) are the orthogonal system of vertical lines; see Figure 7.10.

Next, consider the complex potential function

\[
\chi(z) = \frac{1}{2} z^2 = \frac{1}{2} (x^2 - y^2) + i xy.
\]

The associated complex velocity

\[
f(z) = \chi'(z) = z = x + i y
\]

leads to the hyperbolic flow (7.42). The hyperbolic streamlines \( xy = d \) are the level curves of the stream function \( \psi(x, y) = xy \). The equipotential lines \( \frac{1}{2} (x^2 - y^2) = c \) form a system of orthogonal hyperbolas. Figure 7.11 shows (some of) the equipotentials in the first plot, the stream lines in the second, and combines them together in the third picture.

**Example 7.17. Flow Around a Disk.** Consider the complex potential function

\[
\chi(z) = z + \frac{1}{z} = \left( x + \frac{x}{x^2 + y^2} \right) + i \left( y - \frac{y}{x^2 + y^2} \right).
\]

(7.45)

The corresponding complex fluid velocity is

\[
f(z) = \frac{d\chi}{dz} = 1 - \frac{1}{z^2} = 1 - \frac{x^2 - y^2}{(x^2 + y^2)^2} + i \frac{2 xy}{(x^2 + y^2)^2}.
\]

(7.46)
Figure 7.12. Equipotentials and Streamlines for $z + \frac{1}{z}$.

Figure 7.13. Flow Past a Solid Disk.

The equipotential curves and streamlines are plotted in Figure 7.12. The points $z = \pm 1$ are stagnation points of the flow, while $z = 0$ is a singularity. In particular, fluid particles that move along the positive $x$ axis approach the leading stagnation point $z = 1$ as $t \to \infty$. Note that the streamlines

$$\psi(x, y) = y - \frac{y}{x^2 + y^2} = d$$

are asymptotically horizontal at large distances, and hence, far away from the origin, the flow is indistinguishable from uniform horizontal motion with complex velocity $f(z) \equiv 1$.

The level curve for the particular value $d = 0$ consists of the unit circle $|z| = 1$ and the real axis $y = 0$. In particular, the unit circle $|z| = 1$ consists of two semicircular stream lines combined with the two stagnation points. The flow velocity vector field $\mathbf{v} = \nabla \varphi$ is everywhere tangent to the unit circle, and hence satisfies the no flux condition along the boundary of the unit disk. Thus, we can interpret (7.46), when restricted to the domain $\Omega = \{ |z| > 1 \}$, as the complex velocity of a uniformly moving fluid around the outside of a solid circular disk of radius 1, as illustrated in Figure 7.13. In three dimensions, this would correspond to the steady flow of a fluid around a solid cylinder.
Remark: In this section, we have focused on the fluid mechanical roles of a harmonic function and its conjugate. An analogous interpretation applies when $\varphi(x, y)$ represents an electromagnetic potential function; the level curves of its harmonic conjugate $\psi(x, y)$ are the paths followed by charged particles under the electromotive force field $\mathbf{v} = \nabla \varphi$. Similarly, if $\varphi(x, y)$ represents the equilibrium temperature distribution in a planar domain, its level lines represent the *isotherms* — curves of constant temperature, while the level lines of its harmonic conjugate are the curves along which heat energy flows. Finally, if $\varphi(x, y)$ represents the height of a deformed membrane, then its level curves are the contour lines of elevation. The level curves of its harmonic conjugate are the curves of steepest descent along the membrane, i.e., the paths followed by, say, water flowing down the membrane.

As we now know, complex functions provide an almost inexhaustible supply of harmonic functions, i.e., solutions to the two-dimensional Laplace equation. Thus, to solve an associated boundary value problem, we “merely” find the complex function whose real part matches the prescribed boundary conditions. Unfortunately, even for relatively simple domains, this remains a daunting task.

The one case where we do have an explicit solution is that of a circular disk, where the Poisson integral formula (4.116) provides a complete solution to the Dirichlet boundary value problem. (See also Exercise 4 for the Neumann problem.) Thus, one evident solution strategy for the corresponding boundary value problem on a more complicated domain is to transform it into a solved case by an inspired change of variables.

**Analytic Maps**

The intimate connections between complex analysis and solutions to the Laplace equation inspires us to look at changes of variables defined by complex functions. To this end, we will re-interpret a complex analytic function

$$
\zeta = g(z) \quad \text{or} \quad \xi + i\eta = p(x, y) + i q(x, y)
$$

(7.47)

as a *mapping* that takes a point $z = x + i y$ belonging to a prescribed domain $\Omega \subset \mathbb{C}$ to a point $\zeta = \xi + i\eta$ belonging to the image domain $D = g(\Omega) \subset \mathbb{C}$. In many cases, the image domain $D$ is the unit disk, as in Figure 7.14, but the method can also be applied to more general domains. In order to unambiguously relate functions on $\Omega$ to functions on $D$, we
require that the analytic mapping (7.47) be one-to-one so that each point \( \zeta \in D \) comes from a unique point \( z \in \Omega \). As a result, the inverse function \( z = g^{-1}(\zeta) \) is a well-defined map from \( D \) back to \( \Omega \), which we assume is also analytic on all of \( D \). The calculus formula for the derivative of the inverse function

\[
\frac{d}{d\zeta} g^{-1}(\zeta) = \frac{1}{g'(z)} \quad \text{at} \quad \zeta = g(z),
\]

remains valid for complex functions. It implies that the derivative of \( g(z) \) must be nonzero everywhere in order that \( g^{-1}(\zeta) \) be differentiable. This condition,

\[
g'(z) \neq 0 \quad \text{at every point} \quad z \in \Omega,
\]

will play a crucial role in the development of the method. Finally, in order to match the boundary conditions, we will assume that the mapping extends continuously to the boundary \( \partial \Omega \) and maps it, one-to-one, to the boundary \( \partial D \) of the image domain.

Before trying to apply this idea to solve boundary value problems for the Laplace equation, let us look at some of the most basic examples of analytic mappings.

**Example 7.18.** The simplest nontrivial analytic maps are the translations

\[
\zeta = z + \beta = (x + a) + i (y + b),
\]

where \( \beta = a + i b \) is a fixed complex number. The effect of (7.50) is to translate the entire complex plane in the direction given by the vector \((a, b)\). In particular, the translation maps the disk \( \Omega = \{ |z| < 1 \} \) of radius 1 and center at the point \( -\beta \) to the unit disk \( D = \{ |\zeta| < 1 \} \).

**Example 7.19.** There are two types of linear analytic maps. First are the scalings

\[
\zeta = \rho z = \rho x + i \rho y,
\]

where \( \rho \neq 0 \) is a fixed nonzero real number. This maps the disk \( |z| < 1/|\rho| \) to the unit disk \( |\zeta| < 1 \). Second are the rotations

\[
\zeta = e^{i\varphi} z = (x \cos \varphi - y \sin \varphi) + i (x \sin \varphi + y \cos \varphi),
\]

which rotates the complex plane around the origin by a fixed (real) angle \( \varphi \). These all map the unit disk to itself.

**Example 7.20.** Any non-constant affine transformation

\[
\zeta = \alpha z + \beta, \quad \alpha \neq 0,
\]

defines an invertible analytic map on all of \( \mathbb{C} \), whose inverse \( z = \alpha^{-1}(\zeta - \beta) \) is also affine. Writing \( \alpha = \rho e^{i\phi} \) in polar coordinates, we see that the affine map (7.53) can be viewed as the composition of a rotation (7.52), followed by a scaling (7.51), followed by a translation (7.50). As such, it takes the disk \( |\alpha z + \beta| < 1 \) of radius \( 1/|\alpha| = 1/|\rho| \) and center \(-\beta/\alpha\) to the unit disk \( |\zeta| < 1 \).
Example 7.21. A more interesting example is the complex function
\[ \zeta = g(z) = \frac{1}{z}, \quad \text{or} \quad \xi = \frac{x}{x^2 + y^2}, \quad \eta = -\frac{y}{x^2 + y^2}, \]
which defines an inversion of the complex plane. The inversion is a one-to-one analytic map everywhere except at the origin \( z = 0 \); indeed \( g(z) \) is its own inverse: \( g^{-1}(\zeta) = 1/\zeta \). Since \( g'(z) = -1/z^2 \) is never zero, the derivative condition (7.49) is satisfied everywhere. Note that \( |\zeta| = 1/|z| \), while \( \text{ph } \zeta = -\text{ph } z \). Thus, if \( \Omega = \{ |z| > \rho \} \) denotes the exterior of the circle of radius \( \rho \), then the image points \( \zeta = 1/z \) satisfy \( |\zeta| = 1/|z| \), and hence the image domain is the punctured disk \( D = \{ 0 < |\zeta| < 1/\rho \} \). In particular, the inversion maps the outside of the unit disk to its inside, but with the origin removed, and vice versa. The reader may enjoy seeing what the inversion does to other domains, e.g., the unit square \( S = \{ z = x + iy | 0 < x, y < 1 \} \).

Example 7.22. The complex exponential
\[ \zeta = g(z) = e^z, \quad \text{or} \quad \xi = e^x \cos y, \quad \eta = e^x \sin y, \]
satisfies the condition \( g'(z) = e^z \neq 0 \) everywhere. Nevertheless, it is not one-to-one because \( e^{z+2\pi i} = e^z \), and so points that differ by an integer multiple of \( 2\pi i \) are all mapped to the same point. We conclude that (7.49) is necessary, but not sufficient for invertibility.

Under the exponential map, the horizontal line \( \text{Im } z = b \) is mapped to the curve \( \zeta = e^{x+ib} = e^x (\cos b + i \sin b) \), which, as \( x \) varies from \( -\infty \) to \( \infty \), traces out the ray emanating from the origin that makes an angle \( \text{ph } \zeta = b \) with the real axis. Therefore, the exponential map will map a horizontal strip
\[ S_{a,b} = \{ a < \text{Im } z < b \} \quad \text{to a wedge-shaped domain} \quad \Omega_{a,b} = \{ a < \text{ph } \zeta < b \}, \]
and is one-to-one provided \( |b - a| < 2\pi \). In particular, the horizontal strip
\[ S_{-\pi/2,\pi/2} = \{ -\frac{1}{2} \pi < \text{Im } z < \frac{1}{2} \pi \} \]
of width \( \pi \) centered around the real axis is mapped, in a one-to-one manner, to the right half plane
\[ R = \Omega_{-\pi/2,\pi/2} = \{ -\frac{1}{2} \pi < \text{ph } \zeta < \frac{1}{2} \pi \} = \{ \text{Im } \zeta > 0 \}, \]
\[ \dagger \] This is slightly different than the real inversion (6.128); see Exercise ![Ex].
while the horizontal strip $S_{-\pi,\pi} = \{-\pi < \text{Im } z < \pi\}$ of width $2\pi$ is mapped onto the domain
\[ \Omega_* = \Omega_{-\pi,\pi} = \{-\pi < \text{ph } \zeta < \pi\} = \mathbb{C} \setminus \{\text{Im } z = 0, \text{Re } z \leq 0\} \]
on obtained by cutting the complex plane along the negative real axis.

On the other hand, vertical lines $\text{Re } z = a$ are mapped to circles $|\zeta| = e^a$. Thus, a vertical strip $a < \text{Re } z < b$ is mapped to an annulus $e^a < |\zeta| < e^b$, albeit many-to-one, since the strip is effectively wrapped around and around the annulus. The rectangle $R = \{a < x < b, -\pi < y < \pi\}$ of height $2\pi$ is mapped in a one-to-one fashion on an annulus that has been cut along the negative real axis. See Figure 7.15. Finally, we note that no domain is mapped to the unit disk $D = \{|\zeta| < 1\}$ (or, indeed, any other domain that contains 0) because the exponential function is never zero: $\zeta = e^z \neq 0$.

**Example 7.23.** The squaring map
\[ \zeta = g(z) = z^2, \quad \text{or} \quad \zeta = x^2 - y^2, \quad \eta = 2xy, \quad (7.56) \]
is analytic on all of $\mathbb{C}$, but is not one-to-one. Its inverse is the square root function $z = \sqrt{\zeta}$, which, as we noted in Section 7.1, is doubly-valued, except at the origin $z = 0$. Furthermore, its derivative $g'(z) = 2z$ vanishes at $z = 0$, violating the invertibility condition (7.49). However, once we restrict $g(z)$ to a simply connected subdomain $\Omega$ that does not contain 0, the function $g(z) = z^2$ does define a one-to-one mapping, whose inverse $z = g^{-1}(\zeta) = \sqrt{\zeta}$ is a well-defined, analytic and single-valued branch of the square root function.

The effect of the squaring map on a point $z$ is to square its modulus, $|\zeta| = |z|^2$, while doubling its phase, $\text{ph } \zeta = \text{ph } z^2 = 2 \text{ ph } z$. Thus, for example, the upper right quadrant $Q = \{x > 0, y > 0\}$ is mapped onto the upper half plane
\[ U = g(Q) = \{\eta = \text{Im } \zeta > 0\} = \{0 < \text{ph } \zeta < \frac{1}{2} \pi\} \]
is mapped onto the upper half plane
\[ U = g(Q) = \{\eta = \text{Im } \zeta > 0\} = \{0 < \text{ph } \zeta < \pi\}. \]
The inverse function maps a point $\zeta \in U$ back to its unique square root $z = \sqrt{\zeta}$ that lies in the quadrant $Q$. Similarly, a quarter disk
\[ Q_\rho = \{0 < |z| < \rho, 0 < \text{ph } z < \frac{1}{2} \pi\} \]
of radius $\rho$ is mapped to a half disk
\[ U_{\rho^2} = g(\Omega) = \{0 < |\zeta| < \rho^2, \text{Im } \zeta > 0\} \]
of radius $\rho^2$. On the other hand, the unit square $S = \{0 < x < 1, 0 < y < 1\}$ is mapped to a curvilinear triangular domain, as indicated in Figure 7.16; the edges of the square on

**Figure 7.16.** The Effect of $\zeta = z^2$ on Various Domains.
the real and imaginary axes map to the two halves of the straight base of the triangle, while the other two edges become its curved sides.

**Example 7.24.** A particularly important example is the analytic map

$$\zeta = \frac{z - 1}{z + 1} = \frac{x^2 + y^2 - 1}{(x + 1)^2 + y^2} + i \frac{2y}{(x + 1)^2 + y^2}, \quad (7.57)$$

where we established the formulae for its real and imaginary parts in (7.11). The map is one-to-one with analytic inverse

$$z = \frac{1 + \zeta}{1 - \zeta} = \frac{1 - \xi^2 - \eta^2}{(1 - \xi)^2 + \eta^2} + i \frac{2\eta}{(1 - \xi)^2 + \eta^2}, \quad (7.58)$$

provided $z \neq -1$ and $\zeta \neq 1$. This particular analytic map has the important property of mapping the right half plane $R = \{ x = \text{Re} z > 0 \}$ to the unit disk $D = \{ |\zeta|^2 < 1 \}$. Indeed, by (7.58)

$$|\zeta|^2 = \xi^2 + \eta^2 < 1 \quad \text{if and only if} \quad x = \frac{1 - \xi^2 - \eta^2}{(1 - \xi)^2 + \eta^2} > 0.$$ 

Note that the denominator does not vanish on the interior of the disk $D$.

The complex functions (7.53, 54, 57) are particular examples of linear fractional transformations

$$\zeta = \frac{\alpha z + \beta}{\gamma z + \delta}, \quad (7.59)$$

which form one of the most important classes of analytic maps. Here $\alpha, \beta, \gamma, \delta$ are complex constants, subject only to the restriction

$$\alpha \delta - \beta \gamma \neq 0,$$

since otherwise (7.59) reduces to a trivial constant (and non-invertible) map. (Why?)

**Example 7.25.** The linear fractional transformation

$$\zeta = \frac{z - \alpha}{\overline{\alpha} z - 1}, \quad \text{with} \quad |\alpha| < 1, \quad (7.60)$$

maps the unit disk to itself, moving the origin $z = 0$ to the point $\zeta = \alpha$. To prove this, we note that

$$|z - \alpha|^2 = (z - \alpha)(\overline{z} - \overline{\alpha}) = |z|^2 - \alpha \overline{z} - \overline{\alpha} z + |\alpha|^2,$$

$$|\overline{\alpha} z - 1|^2 = (\overline{\alpha} z - 1)(\alpha \overline{z} - 1) = |\alpha|^2 |z|^2 - \alpha \overline{z} - \overline{\alpha} z + 1.$$ 

Subtracting these two formulae,

$$|z - \alpha|^2 - |\overline{\alpha} z - 1|^2 = (1 - |\alpha|^2)(|z|^2 - 1) < 0, \quad \text{whenever} \quad |z| < 1, \quad |\alpha| < 1.$$ 

Thus, $|z - \alpha| < |\overline{\alpha} z - 1|$, which implies that

$$|\zeta| = \frac{|z - \alpha|}{|\overline{\alpha} z - 1|} < 1 \quad \text{provided} \quad |z| < 1, \quad |\alpha| < 1,$$
and hence, as promised, $\zeta$ lies within the unit disk.

The rotations (7.52) also map the unit disk to itself, while leaving the origin fixed. It can be proved, [3, 118], that the only invertible analytic mappings that take the unit disk to itself are obtained by composing such a linear fractional transformation with a rotation.

**Proposition 7.26.** If $\zeta = g(z)$ is a one-to-one analytic map that takes the unit disk to itself, then

$$g(z) = e^{i\varphi} \frac{z - \alpha}{\alpha z - 1} \quad \text{for some} \quad |\alpha| < 1, \quad -\pi < \varphi \leq \pi.$$ (7.61)

Additional properties of linear fractional transformations are outlined in the exercises.

**Conformality**

A remarkable geometrical property enjoyed by all complex analytic functions is that, at non-critical points, they preserve angles, and therefore define *conformal mappings*. Conformality makes sense for any inner product space, although in practice one usually deals with Euclidean space equipped with the standard dot product.

**Definition 7.27.** A function $g: \mathbb{R}^n \to \mathbb{R}^n$ is called *conformal* if it preserves angles.

But what does it mean to “preserve angles”? In the Euclidean norm, the angle between two vectors is defined by their dot product. However, most analytic maps are nonlinear, and so will not map vectors to vectors since they will typically map straight lines to curves. However, if we interpret “angle” to mean the angle between two curves†, as illustrated in Figure 7.17, then we can make sense of the conformality requirement. Thus, in order to realize complex functions as conformal maps, we first need to understand their effect on curves.

In general, a *curve* $C \in \mathbb{C}$ in the complex plane is parametrized by a complex-valued function

$$z(t) = x(t) + iy(t), \quad a \leq t \leq b,$$ (7.62)

that depends on a *real* parameter $t$. Note that there is no essential difference between a complex plane curve (7.62) and a real plane curve; we have merely switched from vector

---

† Or, more precisely, the angle between their tangent vectors at the point of intersection; see below for details.
notation \( x(t) = (x(t), y(t)) \) to complex notation \( z(t) = x(t) + iy(t) \). All the usual vectorial curve terminology — closed, simple (non-self intersecting), piecewise smooth, etc. — is employed without modification. In particular, the tangent vector to the curve can be identified as the complex number \( \dot{z}(t) = x(t) + iy(t) \), where we use dots to indicated derivatives with respect to the parameter \( t \). Smoothness of the curve is guaranteed by the requirement that \( \dot{z}(t) \neq 0 \).

**Example 7.28.** (a) The curve
\[
z(t) = e^{it} = \cos t + i \sin t, \quad \text{for} \quad 0 \leq t \leq 2\pi,
\]
parametrizes the unit circle \( |z| = 1 \) in the complex plane. Its complex tangent \( \dot{z}(t) = ie^{it} = iz(t) \) is obtained by rotating \( z \) through \( 90^\circ \).

(b) The complex curve
\[
z(t) = \cosh t + i \sinh t = \frac{1+i}{2}e^t + \frac{1-i}{2}e^{-t}, \quad -\infty < t < \infty,
\]
parametrizes the right hand branch of the hyperbola \( \Re z^2 = x^2 - y^2 = 1 \). The complex tangent vector is \( \dot{z}(t) = \sinh t + i \cosh t = i\pi(t) \).

When we interpret the curve as the motion of a particle in the complex plane, so that \( z(t) \) is the position of the particle at time \( t \), the tangent \( \dot{z}(t) \) represents its instantaneous velocity. The modulus of the tangent, \( |\dot{z}| = \sqrt{x^2 + y^2} \), indicates the particle’s speed, while its phase \( \text{ph} \, \dot{z} \) measures the direction of motion, as prescribed by the angle that the curve makes with the horizontal; see Figure 7.18.

The angle between two curves is defined as the angle between their tangents at the point of intersection. If the curve \( C_1 \) has angle \( \theta_1 = \text{ph} \, \dot{z}_1(t_1) \) while the curve \( C_2 \) has angle \( \theta_2 = \text{ph} \, \dot{z}_2(t_2) \) at the common point \( z = z_1(t_1) = z_2(t_2) \), then the angle \( \theta \) between \( C_1 \) and \( C_2 \) at \( z \) is their difference
\[
\theta = \theta_2 - \theta_1 = \text{ph} \, \dot{z}_2 - \text{ph} \, \dot{z}_1 = \text{ph} \left( \frac{\dot{z}_2}{\dot{z}_1} \right). \quad (7.63)
\]

Now, consider the effect of an analytic map \( \zeta = g(z) \). A curve \( C \) parametrized by \( z(t) \) will be mapped to a new curve \( \Gamma = g(C) \) parametrized by the composition \( \zeta(t) = g(z(t)) \).
The tangent to the image curve is related to that of the original curve by the chain rule:

\[
\frac{d\zeta}{dt} = \frac{dg}{dz} \frac{dz}{dt}, \quad \text{or} \quad \dot{\zeta}(t) = g'(z(t)) \dot{z}(t). \tag{7.64}
\]

Therefore, the effect of the analytic map on the tangent vector \( \dot{z} \) is to multiply it by the complex number \( g'(z) \). If the analytic map satisfies our key assumption \( g'(z) \neq 0 \), then \( \dot{\zeta} \neq 0 \), and so the image curve is guaranteed to be smooth.

According to equation (7.64),

\[
|\dot{\zeta}| = |g'(z)\dot{z}| = |g'(z)||\dot{z}|. \tag{7.65}
\]

Thus, the speed of motion along the new curve \( \zeta(t) \) is multiplied by a factor \( \rho = |g'(z)| > 0 \). The magnification factor \( \rho \) depends only upon the point \( z \) and not how the curve passes through it. All curves passing through the point \( z \) are speeded up (or slowed down if \( \rho < 1 \)) by the same factor! Similarly, the angle that the new curve makes with the horizontal is given by

\[
\phi \dot{\zeta} = \phi g'(z) \dot{z} = \phi g'(z) + \phi \dot{z}. \tag{7.66}
\]

Therefore, the tangent angle of the curve is increased by an amount \( \phi = \phi g'(z) \), which means that the tangent is been rotated through angle \( \phi \). Again, the increase in tangent angle only depends on the point \( z \), and all curves passing through \( z \) are rotated by the same amount \( \phi \). As an immediate consequence, the angle between any two curves is preserved.

More precisely, if \( C_1 \) is at angle \( \theta_1 \) and \( C_2 \) at angle \( \theta_2 \) at a point of intersection, then their images \( \Gamma_1 = g(C_1) \) and \( \Gamma_2 = g(C_2) \) are at angles \( \psi_1 = \theta_1 + \phi \) and \( \psi_2 = \theta_2 + \phi \). The angle between the two image curves is the difference

\[
\psi_2 - \psi_1 = (\theta_2 + \phi) - (\theta_1 + \phi) = \theta_2 - \theta_1,
\]

which is the same as the angle between the original curves. This establishes the conformal or angle-preservation property of analytic maps.

**Theorem 7.29.** If \( \zeta = g(z) \) is an analytic function and \( g'(z) \neq 0 \), then \( g \) defines a conformal map.

**Remark:** The converse is also valid: Every planar conformal map comes from a complex analytic function with nonvanishing derivative. A proof is outlined in Exercise 7.

The conformality of analytic functions is all the more surprising when one revisits elementary examples. In Example 7.23, we discovered that the function \( w = z^2 \) maps a quarter plane to a half plane, and therefore doubles the angle between the coordinate axes at the origin! Thus \( g(z) = z^2 \) is most definitely not conformal at \( z = 0 \). The explanation is, of course, that \( z = 0 \) is a critical point, \( g'(0) = 0 \), and Theorem 7.29 only guarantees conformality when the derivative is nonzero. Amazingly, the map preserves angles everywhere else! Somehow, the angle at the origin is doubled, while angles at all nearby points are preserved. Figure 7.19 illustrates this remarkable and counter-intuitive feat. The left hand figure shows the coordinate grid, while on the right are the images of the horizontal and vertical lines under the map \( z^2 \). Note that, except at the origin, the image curves continue to meet at \( 90^\circ \) angles, in accordance with conformality.
Example 7.30. A particularly interesting example is the Joukowski map

\[ \zeta = \frac{1}{2} \left( z + \frac{1}{z} \right). \]  

(7.67)

It was used in the study of flows around airplane wings by the pioneering Russian aero- and hydro-dynamics researcher Nikolai Zhukovskii (Joukowski). Since

\[ \frac{d \zeta}{dz} = \frac{1}{2} \left( 1 - \frac{1}{z^2} \right) = 0 \quad \text{if and only if} \quad z = \pm 1, \]

the Joukowski map is conformal except at the critical points \( z = \pm 1 \), as well as at the singularity \( z = 0 \) where it is not defined.

If \( z = e^{i \theta} \) lies on the unit circle, then

\[ \zeta = \frac{1}{2} \left( e^{i \theta} + e^{-i \theta} \right) = \cos \theta, \]

lies on the real axis, with \( -1 \leq \zeta \leq 1 \). Thus, the Joukowski map squashes the unit circle down to the real line segment \([-1, 1]\). The images of points outside the unit circle fill the

Figure 7.19. Conformality of \( z^2 \).

Figure 7.20. The Joukowski Map.
rest of the $\zeta$ plane, as do the images of the (nonzero) points inside the unit circle. Indeed, if we solve (7.67) for
\[ z = \zeta \pm \sqrt{\zeta^2 - 1}, \]  
we see that every $\zeta$ except $\pm 1$ comes from two different points $z$; for $\zeta$ not on the critical line segment $[-1, 1]$, one point lies inside and and one lies outside the unit circle, whereas if $-1 < \zeta < 1$, the points lie on the unit circle and on a common vertical line. Therefore, (7.67) defines a one-to-one conformal map from the exterior of the unit circle \( \{ |z| > 1 \} \) onto the exterior of the unit line segment $\mathbb{C} \setminus [-1, 1]$.

Under the Joukowski map, the concentric circles $|z| = r \neq 1$ are mapped to ellipses with foci at $\pm 1$ in the $\zeta$ plane; see Figure 7.20. The effect on circles not centered at the origin is quite interesting. The image curves take on a wide variety of shapes; several examples are plotted in Figure 7.21. If the circle passes through the singular point $z = 1$, then its image is no longer smooth, but has a cusp at $\zeta = 1$; this happens in the last 6 of the figures. Some of the image curves have the shape of the cross-section through an airplane wing or airfoil. Later, we will see how to construct the physical fluid flow around such an airfoil, a result that was a critical step in early aircraft design.

*Composition and the Riemann Mapping Theorem*

One of the features of conformal mapping is that one can assemble a large repertoire of complicated examples by simply composing elementary mappings. The method rests on the simple fact that the composition of two complex analytic functions is also complex analytic. This is the complex counterpart of the result, learned in first year calculus, that the composition of two differentiable functions is itself differentiable.
Proposition 7.31. If \( w = f(z) \) is an analytic function of the complex variable \( z = x + iy \), and \( \zeta = g(w) \) is an analytic function of the complex variable \( w = u + iv \), then the composition \( \zeta = h(z) \equiv g \circ f = g(f(z)) \) is an analytic function of \( z \).

The proof that the composition of two differentiable functions is differentiable is identical to the real variable version, \([7, 129]\), and need not be reproduced here. The derivative of the composition is explicitly given by the usual chain rule:

\[
\frac{d}{dz} g \circ f(z) = g'(f(z)) f'(z), \quad \text{or, in Leibnizian notation,} \quad \frac{d\zeta}{dz} = \frac{d\zeta}{dw} \frac{dw}{dz}. \quad (7.69)
\]

If both \( f \) and \( g \) are one-to-one, so is their composition \( h = g \circ f \). Moreover, the composition of two conformal maps is also conformal, a fact that is immediate from the definition, or by using the chain rule (7.69) to show that

\[
h'(z) = g'(f(z)) f'(z) \neq 0 \quad \text{provided} \quad g'(f(z)) \neq 0 \quad \text{and} \quad f'(z) \neq 0.
\]

Example 7.32. As we learned in Example 7.22, the exponential function

\[ w = e^z \]

maps the horizontal strip \( S = \left\{ -\frac{1}{2} \pi < \text{Im} \, z < \frac{1}{2} \pi \right\} \) conformally onto the right half plane \( R = \{ \text{Re} \, w > 0 \} \). On the other hand, Example 7.24 tells us that the linear fractional transformation

\[ \zeta = \frac{w - 1}{w + 1} \]

maps the right half plane \( R \) conformally to the unit disk \( D = \{ |\zeta| < 1 \} \). Therefore, the composition

\[ \zeta = \frac{e^z - 1}{e^z + 1} \quad (7.70) \]

is a one-to-one conformal map from the horizontal strip \( S \) to the unit disk \( D \), which we illustrate in Figure 7.22.

---

† Of course, to properly define the composition, we need to ensure that the range of the function \( w = f(z) \) is contained in the domain of the function \( \zeta = g(w) \).
Recall that our motivating goal is to use analytic functions/conformal maps to solve boundary value problems for the Laplace equation on a complicated domain $\Omega$ by transforming them to boundary value problems on the unit disk. Of course, the key question the student should be asking at this point is: Is there, in fact, a conformal map $\zeta = g(z)$ from a given domain $\Omega$ to the unit disk $D = g(\Omega)$? The theoretical answer is the celebrated Riemann Mapping Theorem.

**Theorem 7.33.** If $\Omega \subsetneq \mathbb{C}$ is any simply connected open subset, not equal to the entire complex plane, then there exists a one-to-one complex analytic map $\zeta = g(z)$, satisfying the conformality condition $g'(z) \neq 0$ for all $z \in \Omega$, that maps $\Omega$ to the unit disk $D = \{ |\zeta| < 1 \}$.

Thus, any simply connected domain — with one exception, the entire complex plane — can be conformally mapped the unit disk. Note that $\Omega$ need not be bounded for this to hold. Indeed, the conformal map (7.57) takes the unbounded right half plane $R = \{ \text{Re } z > 0 \}$ to the unit disk. The proof of this important theorem relies on some more advanced results in complex analysis, and can be found, for instance, in [3].

The Riemann Mapping Theorem guarantees the existence of a conformal map from any simply connected domain to the unit disk, but its proof is not constructive, and so is of little help for constructing the desired mapping. And, in general, this is not an easy task. In practice, one assembles a collection of useful conformal maps that apply to particular domains of interest. An extensive catalog can be found in [74]. More complicated maps can then be built up by composition of the basic examples. Ultimately, though, the determination of a suitable conformal map is more an art than a systematic science.

**Example 7.34.** Suppose we are asked to conformally map the upper half plane $U = \{ \text{Im } z > 0 \}$ to the unit disk $D = \{ |\zeta| < 1 \}$. We already know that the linear fractional transformation

$$
\zeta = g(w) = \frac{w - 1}{w + 1}
$$

maps the right half plane $R = \{ \text{Re } w > 0 \}$ to $D = g(R)$. On the other hand, multiplication by $i = e^{i\pi/2}$, with $z = h(w) = i w$, rotates the complex plane by $90^\circ$ and so maps the right half plane $R$ to the upper half plane $U = h(R)$. Its inverse $h^{-1}(z) = -iz$ will therefore map $U$ to $R = h^{-1}(U)$. Therefore, to map the upper half plane to the unit disk, we compose these two maps, leading to the conformal map

$$
\zeta = g \circ h^{-1}(z) = \frac{-iz - 1}{-iz + 1} = \frac{iz + 1}{iz - 1}
$$

from $U$ to $D$.

In a similar vein, we already know that the squaring map $w = z^2$ maps the upper right quadrant $Q = \{ 0 < \text{ph } z < \frac{1}{2}\pi \}$ to the upper half plane $U$. Composing this with our previously constructed map — which requires replacing $z$ by $w$ in (7.71) beforehand — leads to the conformal map

$$
\zeta = \frac{iz^2 + 1}{iz^2 - 1}
$$

that maps the quadrant $Q$ to the unit disk $D$. 
Example 7.35. The goal of this example is to construct a conformal map that takes a half disk
\[ D_+ = \{ |z| < 1, \ \text{Im} \ z > 0 \} \]  \hspace{1cm} (7.73)
to the full unit disk \( D = \{ |\zeta| < 1 \} \). The answer is not \( \zeta = z^2 \) because the image of \( D_+ \) omits the positive real axis, resulting in a disk that has a slit cut out of it: \( \{ |\zeta| < 1, \ 0 < \text{ph} \ \zeta < 2\pi \} \). To obtain the entire disk as the image of the conformal map, we must think a little harder. The first observation is that the map \( z = (w-1)/(w+1) \) that we analyzed in Example 7.24 takes the right half plane \( R = \{ \text{Re} \ w > 0 \} \) to the unit disk. Moreover, it maps the upper right quadrant \( Q = \{ 0 < \text{ph} \ w < \frac{1}{2} \pi \} \) to the half disk (7.73). Its inverse,
\[ w = \frac{z+1}{z-1} \]  \hspace{1cm} (7.74)
will therefore map the half disk, \( z \in D_+ \), to the upper right quadrant \( w \in Q \).

On the other hand, we just constructed a conformal map (7.72) that takes the upper right quadrant \( Q \) to the unit disk \( D \). Therefore, if compose the two maps — replacing \( z \) by \( w \) in (7.72) and then using (7.74) — we obtain the desired conformal map:
\[ \zeta = \frac{i w^2 + 1}{i w^2 - 1} = \frac{i \left( \frac{z+1}{z-1} \right)^2 + 1}{i \left( \frac{z+1}{z-1} \right)^2 - 1} = \frac{(i+1)(z^2+1) + 2(i-1)z}{(i-1)(z^2+1) + 2(i+1)z}. \]
The formula can be further simplified by multiplying numerator and denominator by \( i+1 \), and so
\[ \zeta = -i \frac{z^2 + 2iz + 1}{z^2 - 2iz + 1}. \]
The leading factor \(-i\) is unimportant and can be omitted, since it merely rotates the disk by \(-90^\circ\), and so
\[ \zeta = \frac{z^2 + 2iz + 1}{z^2 - 2iz + 1} \]  \hspace{1cm} (7.75)
is an equally valid solution to our problem.

Finally, as noted in the preceding example, the conformal map guaranteed by the Riemann Mapping Theorem is not unique. Since the linear fractional transformations (7.60) map the unit disk to itself, we can compose them with any conformal Riemann mapping to produce additional conformal maps from a simply connected domain to the unit disk. For example, composing (7.60) with (7.70) produces a family of mappings
\[ \zeta = \frac{1 + e^2 - \alpha(1-e^2)}{\alpha(1 + e^2) - 1 + e^2}, \]  \hspace{1cm} (7.76)
which, for any \( |\alpha| < 1 \), maps the strip \( S = \{ -\frac{1}{2} \pi < \text{Im} \ z < \frac{1}{2} \pi \} \) onto the unit disk. Proposition 7.26 implies that this is the only ambiguity, and so, for instance, (7.76) forms a complete list of one-to-one conformal maps from \( S \) to \( D \).
Annular Domains

The Riemann Mapping Theorem does not apply to non-simply connected domains. For purely topological reasons, a hole cannot be made to disappear under a one-to-one continuous mapping — much less a conformal map — and so a non-simply connected domain cannot be mapped in a one-to-one manner onto the unit disk. So we must look elsewhere for a simple model domain.

The simplest non-simply connected domain is an annulus consisting of the points between two concentric circles

\[ A_{r,R} = \{ r < |\zeta| < R \}, \quad \text{(7.77)} \]

which, for simplicity, is centered around the origin; see Figure 7.23. The case \( r = 0 \) corresponds to a punctured disk, while setting \( R = \infty \) gives the exterior of a disk of radius \( r \). It can be proved, \[74\], that any other domain with a single hole can be mapped to an annulus. The annular radii \( r, R \) are not uniquely specified; indeed the linear map \( \zeta = \alpha z \) maps the annulus (7.77) to a rescaled annulus \( A_{\rho r,\rho R} \) whose inner and outer radii have both been scaled by the factor \( \rho = |\alpha| \). But the ratio\(^\dagger\) \( r/R \) of the inner to outer radius of the annulus is uniquely specified; annuli with different ratios cannot be mapped to each other by a conformal map.

Example 7.36. Let \( c > 0 \). Consider the domain

\[ \Omega = \{ |z| < 1 \quad \text{and} \quad |z - c| > c \} \]

contained between two nonconcentric circles. To keep the computations simple, we take the outer circle to have radius 1 (which can always be arranged by scaling, anyway) while the inner circle has center at the point \( z = c \) on the real axis and radius \( c \), which means that it passes through the origin. We must restrict \( c < \frac{1}{2} \) in order that the inner circle not overlap with the outer circle. Our goal is to find a conformal map \( \zeta = g(z) \) that takes this non-concentric annular domain to a concentric annulus of the form

\[ A_{r,1} = \{ r < |\zeta| < 1 \}. \]

\(^\dagger\) If \( r = 0 \) or \( R = \infty \), but not both, then \( r/R = 0 \) by convention. The punctured plane, where \( r = 0 \) and \( R = \infty \) remains a separate case.
Now, according to Example 7.25, a linear fractional transformation of the form
\[ \zeta = g(z) = \frac{z - \alpha}{\alpha z - 1} \quad \text{with} \quad |\alpha| < 1 \] (7.78)
maps the unit disk to itself. Moreover, as noted above, and demonstrated in Exercise 7.78, linear fractional transformations always map circles to circles. Therefore, we seek a particular value of \( \alpha \) that maps the inner circle \( |z - c| = c \) to a circle of the form \( |\zeta| = r \) centered at the origin. We choose \( \alpha \) to be real and try to map the points 0 and \( 2c \) on the inner circle to the points \( r \) and \( -r \) on the circle \( |\zeta| = r \). This requires
\[ g(0) = \alpha = r, \quad g(2c) = \frac{2c - \alpha}{2c\alpha - 1} = -r. \] (7.79)
Substituting the first into the second leads to the quadratic equation
\[ c\alpha^2 - \alpha + c = 0. \]
There are two real solutions:
\[ \alpha = \frac{1 - \sqrt{1 - 4c^2}}{2c} \quad \text{and} \quad \alpha = \frac{1 + \sqrt{1 - 4c^2}}{2c}. \] (7.80)
Since \( 0 < c < \frac{1}{2} \), the second solution gives \( \alpha > 1 \), and hence is inadmissible. Therefore, the first solution yields the required conformal map
\[ \zeta = \frac{z - 1 + \sqrt{1 - 4c^2}}{(1 - \sqrt{1 - 4c^2}) z - 2c}. \]
Note in particular that the radius \( r = \alpha \) of the inner circle in \( A_{r,1} \) is not the same as the radius \( c \) of the inner circle in \( \Omega \). For example, taking \( c = \frac{2}{5} \), equation (7.80) implies \( \alpha = \frac{1}{2} \), and hence the linear fractional transformation \( \zeta = \frac{2z - 1}{z - 2} \) maps the annular domain \( \Omega = \{ |z| < 1, \ |z - \frac{2}{5}| > \frac{2}{5} \} \) to the concentric annulus \( A = A_{1/2,1} = \{ \frac{1}{2} < |\zeta| < 1 \} \). In Figure 7.24, we plot several of the non-concentric circles in \( \Omega \) that are mapped to concentric circles in the annulus \( A \).
7.5. Applications of Conformal Mapping.

Let us now apply what we have learned about analytic/conformal maps. We begin with boundary value problems for the Laplace equation, and then present some applications in fluid mechanics. We conclude by discussing how to use conformal maps to construct Green’s functions for the two-dimensional Poisson equation.

Applications to Harmonic Functions and Laplace’s Equation

We are interested in solving a boundary value problem for the Laplace equation on a domain $\Omega \subset \mathbb{R}^2$. Our strategy is to map it to a corresponding boundary value problem on the unit disk $D$ that we know how to solve. To this end, suppose we know a conformal map $\zeta = g(z)$ that takes $z \in \Omega$ to $\zeta \in D$. As we know, the real and imaginary parts of an analytic function $F(\zeta)$ defined on $D$ are harmonic. Moreover, according to Proposition 7.31, the composition $f(z) = F(g(z))$ defines an analytic function whose real and imaginary parts are harmonic functions on $\Omega$. Thus, the conformal mapping can be regarded as a change of variables that preserves the property of harmonicity. In fact, this property does not even require the harmonic function to be the real part of an analytic function, i.e., we need not assume the existence of a harmonic conjugate.

**Proposition 7.37.** If $U(\xi, \eta)$ is a harmonic function of $\xi, \eta$, and

$$\zeta = \xi + i \eta = \xi(x, y) + i \eta(x, y) = g(z)$$

is any analytic function, then the composition

$$u(x, y) = U(\xi(x, y), \eta(x, y))$$

is a harmonic function of $x, y$.

**Proof**: This is a straightforward application of the chain rule:

$$\frac{\partial u}{\partial x} = \frac{\partial U}{\partial \xi} \frac{\partial \xi}{\partial x} + \frac{\partial U}{\partial \eta} \frac{\partial \eta}{\partial x}, \quad \frac{\partial u}{\partial y} = \frac{\partial U}{\partial \xi} \frac{\partial \xi}{\partial y} + \frac{\partial U}{\partial \eta} \frac{\partial \eta}{\partial y};$$

$$\frac{\partial^2 u}{\partial x^2} = \frac{\partial^2 U}{\partial \xi^2} \left( \frac{\partial \xi}{\partial x} \right)^2 + 2 \frac{\partial^2 U}{\partial \xi \partial \eta} \frac{\partial \xi}{\partial x} \frac{\partial \eta}{\partial x} + \frac{\partial^2 U}{\partial \eta^2} \left( \frac{\partial \eta}{\partial x} \right)^2 + \frac{\partial U}{\partial \xi} \frac{\partial^2 \xi}{\partial x^2} + \frac{\partial U}{\partial \eta} \frac{\partial^2 \eta}{\partial x^2},$$

$$\frac{\partial^2 u}{\partial y^2} = \frac{\partial^2 U}{\partial \xi^2} \left( \frac{\partial \xi}{\partial y} \right)^2 + 2 \frac{\partial^2 U}{\partial \xi \partial \eta} \frac{\partial \xi}{\partial y} \frac{\partial \eta}{\partial y} + \frac{\partial^2 U}{\partial \eta^2} \left( \frac{\partial \eta}{\partial y} \right)^2 + \frac{\partial U}{\partial \xi} \frac{\partial^2 \xi}{\partial y^2} + \frac{\partial U}{\partial \eta} \frac{\partial^2 \eta}{\partial y^2}.$$  

Using the Cauchy–Riemann equations

$$\frac{\partial \xi}{\partial x} = - \frac{\partial \eta}{\partial y}, \quad \frac{\partial \xi}{\partial y} = \frac{\partial \eta}{\partial x},$$

for the analytic function $\zeta = \xi + i \eta$, we find, after some algebra,

$$\Delta u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = \left( \frac{\partial \xi}{\partial x} \right)^2 \left( \frac{\partial \eta}{\partial x} \right)^2 \left[ \frac{\partial^2 U}{\partial \xi^2} + \frac{\partial^2 U}{\partial \eta^2} \right] = |g'(z)|^2 \Delta U,$$  

(7.83)
where \( g'(z)^2 = (\partial \xi / \partial x)^2 + (\partial \eta / \partial x)^2 \). We conclude that whenever \( U(\xi, \eta) \) is any harmonic function, and so solves the Laplace equation \( \Delta U = 0 \) (in the \( \xi, \eta \) variables), then \( u(x, y) \) is a solution to the Laplace equation \( \Delta u = 0 \) in the \( x, y \) variables, and is thus also harmonic. \( \text{Q.E.D.} \)

This observation has immediate consequences for boundary value problems arising in physical applications. Suppose we wish to solve the Dirichlet problem

\[
\Delta u = 0 \quad \text{in} \quad \Omega, \quad u = h \quad \text{on} \quad \partial \Omega, \tag{7.84}
\]
on a simply connected domain \( \Omega \subseteq \mathbb{C} \). Let \( \zeta = g(z) = p(x, y) + i q(x, y) \) be a one-to-one conformal mapping from the domain \( \Omega \) to the unit disk \( D \), whose existence is guaranteed by the Riemann Mapping Theorem 7.33. (Although its explicit construction may be problematic.) Then the change of variables formula (7.82) will map the harmonic function \( u(x, y) \) on \( \Omega \) to a harmonic function \( U(\xi, \eta) \) on \( D \). Moreover, the boundary values of \( U = H \) on the unit circle \( \partial D \) correspond to those of \( u = h \) on \( \partial \Omega \) by the same change of variables formula:

\[
h(x, y) = H(p(x, y), q(x, y)), \quad \text{for} \quad (x, y) \in \partial \Omega. \tag{7.85}
\]

We conclude that \( U(\xi, \eta) \) solves the Dirichlet problem

\[
\Delta U = 0 \quad \text{in} \quad D, \quad U = H \quad \text{on} \quad \partial D. \tag{7.86}
\]

But we already know how to solve the Dirichlet problem (7.86) on the unit disk by the Poisson integral formula (4.116)! We conclude that the solution to the original boundary value problem is given by the composition formula \( u(x, y) = U( p(x, y), q(x, y) ) \). In summary, the solution to the Dirichlet problem on a unit disk can be used to solve the Dirichlet problem on more complicated planar domains — provided we are in possession of an appropriate conformal map.

**Example 7.38.** According to Example 7.24, the analytic function

\[
\xi + i \eta = \zeta = \frac{z - 1}{z + 1} = \frac{x^2 + y^2 - 1}{(x + 1)^2 + y^2} + i \frac{2y}{(x + 1)^2 + y^2} \tag{7.87}
\]

maps the right half plane \( R = \{ x = \text{Re} \, z > 0 \} \) to the unit disk \( D = \{ |\zeta| < 1 \} \). Proposition 7.37 implies that if \( U(\xi, \eta) \) is a harmonic function in the unit disk, then

\[
u(x, y) = U \left( \frac{x^2 + y^2 - 1}{(x + 1)^2 + y^2}, \frac{2y}{(x + 1)^2 + y^2} \right) \tag{7.88}
\]
is a harmonic function on the right half plane. (This can, of course, be checked directly by a rather unpleasant chain rule computation.)

To solve the Dirichlet boundary value problem

\[
\Delta u = 0, \quad x > 0, \quad u(0, y) = h(y), \tag{7.89}
\]
on the right half plane, we adopt the change of variables (7.87) and use the Poisson integral formula to construct the solution to the transformed Dirichlet problem

\[
\Delta U = 0, \quad \xi^2 + \eta^2 < 1, \quad U(\cos \varphi, \sin \varphi) = H(\varphi), \tag{7.90}
\]
on the unit disk. The relevant boundary conditions are found as follows. Using the explicit form

\[ x + iy = z = \frac{1 + \zeta}{1 - \zeta} = \frac{(1 + \zeta)(1 - \overline{\zeta})}{|1 - \zeta|^2} = \frac{1 + \zeta - \overline{\zeta} - |\zeta|^2}{|1 - \zeta|^2} = \frac{1 - \xi^2 - \eta^2 + 2i\eta}{(\xi - 1)^2 + \eta^2} \]

for the inverse map, we see that the boundary point \( \zeta = \xi + i\eta = e^{i\varphi} \) on the unit circle \( \partial D \) will correspond to the boundary point

\[ iy = \frac{2\eta}{(\xi - 1)^2 + \eta^2} = \frac{2\sin \varphi}{(\cos \varphi - 1)^2 + \sin^2 \varphi} = i \cot \frac{\varphi}{2} \tag{7.91} \]

on the imaginary axis \( \partial R = \{ \text{Re} \ z = 0 \} \). Thus, the boundary data \( h(y) \) on \( \partial R \) corresponds to the boundary data

\[ H(\varphi) = h(\cot \frac{\varphi}{2}) \]

on the unit circle. The Poisson integral formula (4.116) can then be applied to solve (7.90), from which we are able to reconstruct the solution (7.88) to the boundary value problem (7.88) on the half plane.

Let’s look at an explicit example. If the boundary data on the imaginary axis is provided by the step function

\[ u(0, y) = h(y) \equiv \begin{cases} 1, & y > 0, \\ 0, & y < 0, \end{cases} \]

then the corresponding boundary data on the unit disk is a (periodic) step function

\[ H(\varphi) = \begin{cases} 1, & 0 < \varphi < \pi, \\ 0, & -\pi < \varphi < 0. \end{cases} \]

According to (4.119), the corresponding solution in the unit disk is

\[ U(\xi, \eta) = \begin{cases} 1 - \frac{1}{\pi} \tan^{-1} \left( \frac{1 - \xi^2 - \eta^2}{2\eta} \right), & \xi^2 + \eta^2 < 1, \ \eta > 0, \\ \frac{1}{2}, & \xi^2 + \eta^2 < 1, \ \eta = 0, \\ -\frac{1}{\pi} \tan^{-1} \left( \frac{1 - \xi^2 - \eta^2}{2\eta} \right), & \xi^2 + \eta^2 < 1, \ \eta < 0. \end{cases} \]

After some tedious algebra, we find that the corresponding solution in the right half plane is simply

\[ u(x, y) = \frac{1}{2} + \frac{1}{\pi} \ \text{ph} \ z = \frac{1}{2} + \frac{1}{\pi} \tan^{-1} \frac{y}{x}, \]

an answer that, in hindsight, we should have been able to guess.

\textbf{Remark}: The solution to the preceding Dirichlet boundary value problem is not, in fact, unique, owing to the unboundedness of the domain. The solution that we pick out by using the conformal map to the unit disk is the one that remains bounded at \( \infty \). The unbounded solutions would correspond to solutions on the unit disk that have a singularity in their boundary data at the point \(-1\); see Exercise \( \blacksquare \).
Example 7.39. A non-coaxial cable. The goal of this example is to determine the electrostatic potential inside a non-coaxial cylindrical cable, as illustrated in Figure 7.25, with prescribed constant potential values on the two bounding cylinders. Assume for definiteness that the larger cylinder has radius 1, and is centered at the origin, while the smaller cylinder has radius \( \frac{2}{5} \), and is centered at \( z = \frac{2}{5} \). The resulting electrostatic potential will be independent of the longitudinal coordinate, and so can be viewed as a planar potential in the annular domain contained between two circles representing the cross-sections of our cylinders. The desired potential must satisfy the Dirichlet boundary value problem

\[
\Delta u = 0 \quad \text{when} \quad |z| < 1 \quad \text{and} \quad |z - \frac{2}{5}| > \frac{2}{5},
\]

\[
u = a, \quad \text{when} \quad |z| = 1, \quad \text{and} \quad u = b \quad \text{when} \quad |z - \frac{2}{5}| = \frac{2}{5}.
\]

According to Example 7.36, the linear fractional transformation

\[
\zeta = \frac{2z - 1}{z - 2}
\]

(7.92)

maps this non-concentric annular domain to the annulus \( A_{1/2,1} = \{ \frac{1}{2} < |\zeta| < 1 \} \), which is the cross-section of a coaxial cable. The corresponding transformed potential \( U(\xi, \eta) \) has the constant Dirichlet boundary conditions

\[
U = a, \quad \text{when} \quad |\zeta| = \frac{1}{2}, \quad \text{and} \quad U = b \quad \text{when} \quad |\zeta| = 1.
\]

(7.93)

Clearly the coaxial potential \( U \) must be a radially symmetric solution to the Laplace equation, and hence, according to (6.103), of the form

\[
U(\xi, \eta) = \alpha \log |\zeta| + \beta,
\]

for constants \( \alpha, \beta \). A short computation shows that the particular potential function

\[
U(\xi, \eta) = \frac{b - a}{\log 2} \log |\zeta| + b = \frac{b - a}{2\log 2} \log(\xi^2 + \eta^2) + b
\]

satisfies the prescribed boundary conditions (7.93). Therefore, the desired non-coaxial electrostatic potential

\[
u(x, y) = \frac{b - a}{\log 2} \log \left| \frac{2z - 1}{z - 2} \right| + b = \frac{b - a}{2\log 2} \log \left( \frac{(2x - 1)^2 + y^2}{(x - 2)^2 + y^2} \right) + b
\]

(7.94)
Figure 7.26. Electrostatic Potential Between Coaxial and Non-Coaxial Cylinders.

Figure 7.27. Cross Section of Cylindrical Object.

is obtained by composition with the conformal map (7.92). The particular case $a = 0$, $b = 1$, is plotted in Figure 7.26.

Remark: The same harmonic function determines the equilibrium temperature of an annular plate whose inner boundary is kept at a temperature $u = a$ while the outer boundary is kept at temperature $u = b$. One could also interpret this solution as the equilibrium temperature of a three-dimensional cylindrical body contained between two non-coaxial cylinders that are held at fixed temperatures. The body’s temperature (7.94) only depends upon the transverse coordinates $x, y$, and not upon the longitudinal coordinate $z$.

Applications to Fluid Flow

Conformal mappings are particularly useful in the analysis of planar ideal fluid flow. Let $\Theta(\zeta) = \Phi(\xi, \eta) + i \Psi(\xi, \eta)$ be an analytic function representing the complex potential function for a steady state fluid flow in a planar domain $\zeta \in D$. Composing the complex potential $\Theta(\zeta)$ with a one-to-one conformal map $\zeta = g(z)$ leads to a transformed complex potential $\chi(z) = \Theta(g(z)) = \varphi(x, y) + i \psi(x, y)$ on the corresponding domain $\Omega = g^{-1}(D)$. Thus, we can employ conformal maps to construct fluid flows in complicated domains from known flows in simpler domains.

Let us concentrate on fluid flow past a solid object. The ideal flow assumptions of incompressibility and irrotationality are reasonably accurate if the flow is laminar,
meaning far away from turbulent. In three dimensions, the object is assumed to have a uniform shape in the axial direction, and so we can restrict our attention to a planar fluid flow around a closed, bounded subset \( D \subset \mathbb{R}^2 \cong \mathbb{C} \) representing the cross-section of our cylindrical object, as in Figure 7.27. The (complex) velocity and potential are defined on the complementary domain \( \Omega = \mathbb{C} \setminus D \) occupied by the fluid. The velocity potential \( \varphi(x, y) \) will satisfy the Laplace equation \( \Delta \varphi = 0 \) in the exterior domain \( \Omega \). For a solid object, we should impose the homogeneous Neumann boundary conditions

\[
\frac{\partial \varphi}{\partial n} = 0 \quad \text{on the boundary} \quad \partial \Omega = \partial D, \tag{7.95}
\]

indicating that there is no fluid flux into the object. We note that, according to Exercise 1, a conformal map will automatically preserve the Neumann boundary conditions.

In addition, since the flow is taking place on an unbounded domain, we need to specify the fluid motion at large distances. We shall assume our object is placed in a uniform horizontal flow, e.g., a wind tunnel, as sketched in Figure 7.28. Thus, far away, the object will not affect the flow, and so the velocity should approximate the uniform velocity field \( \mathbf{v} = (1, 0) \), where, for simplicity, we choose our physical units so that the asymptotic speed of the fluid is equal to 1. Equivalently, the velocity potential should satisfy

\[
\varphi(x, y) \approx x, \quad \text{so} \quad \nabla \varphi \approx (1, 0) \quad \text{when} \quad x^2 + y^2 \gg 0.
\]

An alternative physical interpretation is that we are located on an object that is moving horizontally at unit speed through a fluid that is initially at rest. Think of an airplane flying through the air at constant speed. If we adopt a moving coordinate system by sitting inside the airplane, then the effect is as if the plane is sitting still while the air is moving towards us at unit speed.

**Example 7.40.** *Horizontal plate.* The simplest example is a flat plate moving horizontally through the fluid. The plate’s cross-section is a horizontal line segment, and, for simplicity, we take it to be the segment \( D = [-1, 1] \) lying on the real axis. If the plate is very thin and smooth, it will have no appreciable effect on the horizontal flow of the fluid, and, indeed, the velocity potential is given by

\[
\varphi(x, y) = x, \quad \text{for} \quad x + iy \in \Omega = \mathbb{C} \setminus [-1, 1].
\]
Note that $\nabla \varphi = (1, 0)$, and hence this flow satisfies the Neumann boundary conditions (7.95) on the horizontal segment $D = \partial \Omega$. The corresponding complex potential is $\chi(z) = z$, with complex velocity $f(z) = \chi'(z) = 1$.

**Example 7.41. Circular disk.** Recall that the Joukowski conformal map

$$
\zeta = g(z) = \frac{1}{2} \left( z + \frac{1}{z} \right)
$$

(7.96)
squashes the unit circle $|z| = 1$ down to the real line segment $[-1, 1]$ in the $\zeta$ plane. Therefore, it will map the fluid flow outside a unit disk to the fluid flow past the line segment, which, according to the previous example, has complex potential $\Theta(\zeta) = \zeta$. The resulting complex potential is

$$
\chi(z) = \Theta \circ g(z) = g(z) = \frac{1}{2} \left( z + \frac{1}{z} \right).
$$

(7.97)

Except for a factor of $\frac{1}{2}$, indicating that the corresponding flow past the disk is half as fast, this agrees with the potential we derived in Example 7.17.

**Example 7.42. Tilted plate.** Let us next consider the case of a tilted plate in a uniformly horizontal fluid flow. Thus, the cross-section is the line segment

$$
z(t) = t e^{i\phi}, \quad -1 \leq t \leq 1,
$$

obtained by rotating the horizontal line segment $[-1, 1]$ through an angle $\phi$, as in Figure 7.29. The goal is to construct a fluid flow past the tilted segment that is asymptotically horizontal at large distance.

The critical observation is that, while the effect of rotating a plate in a fluid flow is not so evident, rotating a circularly symmetric disk has no effect on in the flow around it. Thus, the rotation $w = e^{-i\phi} z$ maps the disk potential (7.45) to the complex potential

$$
\Upsilon(w) = \chi(e^{i\phi} w) = e^{i\phi} w + \frac{e^{-i\phi}}{w}.
$$

(7.98)
The streamlines of the induced flow are no longer asymptotically horizontal, but rather at an angle $-\phi$. If we now apply the original Joukowski map (7.96) to the rotated flow, the circle is again squashed down to the horizontal line segment, but the flow lines continue to be at angle $-\phi$ at large distances. Thus, if we then rotate the resulting flow through an angle $\phi$, the net effect will be to tilt the segment to the desired angle $\phi$ while rotating the streamlines to be asymptotically horizontal. Putting the pieces together, we deduce the final complex potential to be of the form

$$\chi(z) = e^{i\phi} \left( z \cos \phi - i \sin \phi \sqrt{z^2 - e^{-2i\phi}} \right). \quad (7.99)$$

Sample streamlines for the flow at several attack angles are plotted in Figure 7.29.

**Example 7.43. Airfoils.** As we discovered in Example 7.30, applying the Joukowski map to off-center disks will, in favorable configurations, produce airfoil-shaped objects. The fluid motion around such airfoils can thus be obtained from the flow past such an off-center circle.

First, an affine map

$$w = \alpha z + \beta$$

has the effect of moving the unit disk $|z| \leq 1$ to the disk

$$|w - \beta| \leq |\alpha| \quad (7.100)$$

with center $\beta$ and radius $|\alpha|$. In particular, the boundary circle will continue to pass through the point $w = 1$ provided $|\alpha| = |1 - \beta|$. Moreover, as noted in Example 7.20, the angular component of $\alpha$ has the effect of a rotation, and so the streamlines around the new disk will, asymptotically, be at an angle $\varphi = \theta \alpha$ with the horizontal. We then apply the Joukowski transformation

$$\zeta = \frac{1}{2} \left( w + \frac{1}{w} \right) = \frac{1}{2} \left( \alpha z + \beta + \frac{1}{\alpha z + \beta} \right) \quad (7.101)$$

to map the disk (7.100) to the airfoil shape. The resulting complex potential for the flow past the airfoil is obtained by substituting the inverse map

$$z = \frac{w - \beta}{\alpha} = \frac{\zeta - \beta + \sqrt{\zeta^2 - 1}}{\alpha},$$

into the disk potential (7.45), whereby

$$\Theta(\zeta) = \frac{\zeta - \beta + \sqrt{\zeta^2 - 1}}{\alpha} + \frac{\alpha(\zeta - \beta - \sqrt{\zeta^2 - 1})}{\beta^2 + 1 - 2\beta \zeta}.$$  

Finally, to make the streamlines asymptotically horizontal, we multiply the final result by $e^{i\varphi}$ to rotate back by an angle $-\varphi$, and thus obtain an airfoil tilted by this angle in a horizontal flow. Sample streamlines for the airfoil generated by the circle with center $-1 + .2i$ passing through 1 at several attack angles are graphed in Figure 7.30.
Unfortunately, there is a major flaw with the airfoils that we have just designed. As we will discover, potential flows do not produce lift, and hence an airplane with such a wing would not fly. Fortunately for us, the physical flow is not of this nature! In order to understand how lift enters into the picture, we need to study complex integration, and this will be the topic of the final section of this chapter.

**Poisson’s Equation and the Green’s Function**

Although designed for solving the homogeneous Laplace equation, the method of conformal mapping can also be used to solve its inhomogeneous counterpart — the Poisson equation. As we learned in Chapter 6, to solve an inhomogeneous boundary value problem it suffices to solve the problem when the right hand side is a delta function concentrated at a single point in the domain:

$$-\Delta u = \delta(\zeta(x,y)) = \delta(x-\xi)\delta(y-\eta), \quad \zeta = \xi + i\eta \in \Omega,$$

subject to homogeneous boundary conditions (Dirichlet or mixed) on \(\partial\Omega\). (As usual, we exclude pure Neumann boundary conditions due to lack of existence/uniqueness.) The solution

$$u(x,y) = G_\zeta(x,y) = G(x,y;\xi,\eta)$$

is the *Green’s function* for the given boundary value problem. With the Green’s function in hand, the solution to the homogeneous boundary value problem under a general external forcing,

$$-\Delta u = f(x,y),$$

is then provided by the superposition principle

$$u(x,y) = \int\int_{\Omega} G(x,y;\xi,\eta) f(\xi,\eta) \, d\xi \, d\eta. \quad (7.102)$$

For the planar Poisson equation, the starting point is the logarithmic potential function

$$u(x,y) = \text{Re} \frac{1}{2\pi} \log z = \frac{1}{2\pi} \log |z| = \frac{1}{4\pi} \log(x^2 + y^2), \quad (7.103)$$

which solves the Dirichlet problem

$$-\Delta u = \delta(x,y), \quad (x,y) \in D, \quad u = 0 \quad \text{on} \quad \partial D,$$
on the unit disk $D$ for an impulse concentrated at the origin; see Section 6.3 for details. How do we obtain the corresponding solution when the unit impulse is concentrated at another point $\zeta = \xi + i \eta \in D$ instead of the origin? According to Example 7.25, the linear fractional transformation

$$w = g(z) = \frac{z - \zeta}{\zeta z - 1}, \quad \text{where} \quad |\zeta| < 1,$$

(7.104)

maps the unit disk to itself, moving the point $z = \zeta$ to the origin $w = g(\zeta) = 0$. The logarithmic potential $U = -\frac{1}{2\pi} \log |w|$ will thus be mapped to the Green’s function

$$G(x, y; \xi, \eta) = \frac{1}{2\pi} \log \left| \frac{\overline{\zeta} z - 1}{z - \zeta} \right|$$

(7.105)

at the point $\zeta = \xi + i \eta$. Indeed, by the properties of conformal mapping, since $U$ is harmonic except at the singularity $w = 0$, the function (7.105) will also be harmonic except at the image point $z = \zeta$. Furthermore, as you are asked to prove in Exercise 1, the conformal mapping preserves the delta function singularity in $-\Delta G$. Finally, since the conformal map does not alter the boundary $|z| = 1$, the function (7.105) continues to satisfy the homogeneous Dirichlet boundary conditions there.

Formula (7.105) reproduces the Poisson formula (6.131) for the Green’s function that we previously derived by the method of images. This identification can be verified by substituting $z = re^{i\theta}, \zeta = \rho e^{i\varphi}$, or, more simply, by noting that the denominator in the logarithmic fraction gives the potential due to a unit impulse at $z = \zeta$, while the numerator represents the image potential at $z = 1/\overline{\zeta}$ required to cancel out the effect of the interior potential on the boundary of the unit disk.

Now that we know the Green’s function on the unit disk, we can use the methods of conformal mapping to produce the Green’s function for any other simply connected domain $\Omega \subseteq \mathbb{C}$.

**Proposition 7.44.** Let $w = g(z)$ denote a conformal map that takes the simply connected domain $z \in \Omega$ to the unit disk $w \in D$. Then the Green’s function for the homogeneous Dirichlet boundary problem for the Poisson equation on $\Omega$ is explicitly given by

$$G(z; \zeta) = \frac{1}{2\pi} \log \left| \frac{g(z) - g(\zeta)}{g(\zeta) g(z) - 1} \right|. \quad (7.106)$$

**Example 7.45.** According to Example 7.24, the analytic function

$$w = \frac{z - 1}{z + 1}$$

maps the right half plane $x = \text{Re } z > 0$ to the unit disk $|\zeta| < 1$. Therefore, by (7.106),
the Green’s function for the right half plane has the form

\[
G(z; \zeta) = \frac{1}{2\pi} \log \left| \frac{z - 1 - \zeta - 1}{z + 1 - \zeta + 1} \right| = \frac{1}{2\pi} \log \left| \frac{(\zeta + 1)(z - \zeta)}{(z + 1)(\zeta - \zeta)} \right|. \tag{7.107}
\]

One can then write the solution to the Poisson equation on the right half plane as a superposition, as in (7.102).

7.6. Complex Integration.

The magic and power of calculus ultimately rests on the amazing fact that differentiation and integration are mutually inverse operations. And, just as complex functions enjoy remarkable differentiability properties not shared by their real counterparts, so the sublime beauty of complex integration goes far beyond its more mundane real progenitor. The last section of this chapter is devoted to developing the basics of complex integration theory and presenting a few of its myriad applications.

Let us begin by motivating the definition of the complex integral. As you know, the (definite) integral of a real function, \( \int_a^b f(t) \, dt \), is evaluated on an interval \([a, b] \subset \mathbb{R}\). In complex function theory, integrals are taken along curves in the complex plane, and are akin to the line integrals appearing in real vector calculus. Indeed, the identification of a complex number \( z = x + iy \) with a planar vector \( \mathbf{x} = (x, y) \) will serve to connect the two theories.

Consider a curve \( C \) in the complex plane, parametrized by \( z(t) = x(t) + iy(t) \) for \( a \leq t \leq b \). We define the integral of the complex function \( f(z) \) along the curve \( C \) to be the complex number

\[
\int_C f(z) \, dz = \int_a^b f(z(t)) \frac{dz}{dt} \, dt, \tag{7.108}
\]

the right hand side being an ordinary real integral of a complex-valued function. We shall always assume that the integrand \( f(z) \) is a well-defined complex function at each point on the curve. Let us write out the integrand

\[ f(z) = u(x, y) + i v(x, y) \]

in terms of its real and imaginary parts. Also,

\[ dz = \frac{dz}{dt} \, dt = \left( \frac{dx}{dt} + i \frac{dy}{dt} \right) \, dt = dx + i \, dy. \]

As a result, the complex integral (7.108) splits up into a pair of real line integrals:

\[
\int_C f(z) \, dz = \int_C (u + i v)(dx + i \, dy) = \int_C (u \, dx - v \, dy) + i \int_C (v \, dx + u \, dy). \tag{7.109}
\]
Example 7.46. Suppose \( n \) is an integer. Let us compute complex integrals

\[
\int_C z^n \, dz
\]

of the monomial function \( f(z) = z^n \) along several different curves. We begin with a straight line segment \( I \) along the real axis connecting the points \(-1\) to \(1\), which we parametrize by \( z(t) = t \) for \(-1 \leq t \leq 1\). The defining formula (7.108) implies that the complex integral (7.110) reduces to a real integral:

\[
\int_I z^n \, dz = \int_{-1}^{1} t^n \, dt = \begin{cases} 
0, & n = 2k + 1 > 0 \text{ is odd,} \\
\frac{2}{n+1}, & n = 2k \geq 0 \text{ is even.}
\end{cases}
\]

If \( n \leq -1 \) is negative, then the singularity of the integrand at the origin implies that the integral diverges, and so the complex integral is not defined.

Let us evaluate the same complex integral, but now along a parabolic arc \( P \) parametrized by

\[
z(t) = t + i(t^2 - 1), \quad -1 \leq t \leq 1.
\]

Note that, as we see in Figure 7.31, the parabola connects the same two points in \( \mathbb{C} \). We again refer back to the basic definition (7.108) to evaluate the integral, so

\[
\int_P z^n \, dz = \int_{-1}^{1} \left[ t + i(t^2 - 1) \right]^{n+1} (1 + 2i \, t) \, dt.
\]

We could, at this point, expand the resulting complex polynomial integrand, and then integrate term by term. A more elegant approach is to recognize that it is an exact derivative:

\[
\frac{d}{dt} \left[ t + i(t^2 - 1) \right]^{n+1} \frac{1}{n+1} = \left[ t + i(t^2 - 1) \right]^n (1 + 2i \, t),
\]
as long as \( n \neq -1 \). Therefore, we can use the Fundamental Theorem of Calculus (which works equally well for real integrals of complex-valued functions), to evaluate

\[
\int_P z^n \, dz = \left[ \frac{t + i(t^2 - 1)}{n + 1} \right]^{1\, t = -1}_t = \begin{cases}
0, & -1 \neq n = 2k + 1 \text{ odd,} \\
\frac{2}{n + 1}, & n = 2k \text{ even.}
\end{cases}
\]

Thus, when \( n \geq 0 \) is a positive integer, we obtain the same result as before. Interestingly, in this case the complex integral is well-defined even when \( n \) is a negative integer because, unlike the real line segment, the parabolic path does not go through the singularity of \( z^n \) at \( z = 0 \). The case \( n = -1 \) needs to be done slightly differently, and integration of \( 1/z \) along the parabolic path is left as an exercise for the reader — one that requires some care. We recommend trying the exercise now, and then verifying your answer once we have become a little more familiar with basic complex integration techniques.

Finally, let us try integrating around a semi-circular arc, again with the same endpoints \(-1\) and \(1\). If we parametrize the semi-circle \( S^+ \) by \( z(t) = e^{it}, 0 \leq t \leq \pi \), we find

\[
\int_{S^+} z^n \, dz = \int_0^\pi z^n \, \frac{dz}{dt} \, dt = \int_0^\pi e^{int} e^{it} \, dt = \int_0^\pi e^{i(n+1)t} \, dt = \frac{e^{i(n+1)t}}{n + 1} \bigg|_{t=0}^{\pi} = \begin{cases}
0, & -1 \neq n = 2k + 1 \text{ odd,} \\
-\frac{2}{n + 1}, & n = 2k \text{ even.}
\end{cases}
\]

This value is the negative of the previous cases — but this can be explained by the fact that the circular arc is oriented to go from \(1\) to \(-1\) whereas the line segment and parabola both go from \(-1\) to \(1\). Just as with line integrals, the direction of the curve determines the sign of the complex integral; if we reverse direction, replacing \( t \) by \(-t\), we end up with the same value as the preceding two complex integrals. Moreover — again provided \( n \neq -1 \) — it does not matter whether we use the upper semicircle or lower semicircle to go from \(-1\) to \(1\) — the result is exactly the same. However, the case \( n = -1 \) is an exception to this “rule”. Integrating along the upper semicircle \( S^+ \) from \(1\) to \(-1\) yields

\[
\int_{S^+} \frac{dz}{z} = \int_0^\pi i \, dt = \pi i, \quad (7.111)
\]

whereas integrating along the lower semicircle \( S^- \) from \(1\) to \(-1\) yields the negative

\[
\int_{S^-} \frac{dz}{z} = \int_0^{-\pi} i \, dt = -\pi i. \quad (7.112)
\]

Hence, when integrating the function \(1/z\), it makes a difference which direction we go around the origin.

Integrating \( z^n \) for any integer \( n \neq -1 \) around an entire circle gives zero — irrespective of the radius. This can be seen as follows. We parametrize a circle of radius \( r \) by \( z(t) = re^{it} \) for \( 0 \leq t \leq 2\pi \). Then, by the same computation,

\[
\oint_C z^n \, dz = \int_0^{2\pi} (r^n e^{int})(ri e^{it}) \, dt = \int_0^{2\pi} i r^{n+1} e^{i(n+1)t} \, dt = \frac{r^{n+1}}{n + 1} e^{i(n+1)t} \bigg|_{t=0}^{2\pi} = 0, \quad (7.113)
\]

\[
\int_C \frac{dz}{z} = \pi i, \quad (7.114)
\]

\[
\oint_C \frac{dz}{z^n} = \frac{2\pi i}{(n - 1)!}, \quad (7.115)
\]

\[
\oint_C \frac{dz}{z^n - a^n} = \frac{2\pi i}{n \cdot a^{n-1}}, \quad (7.116)
\]

\[
\oint_C \frac{dz}{z^n + a^n} = 0, \quad (7.117)
\]

\[
\oint_C \frac{dz}{z^n} = \frac{2\pi i}{n \cdot a^{n-1}} \quad \text{if} \quad a \neq 0, \quad (7.118)
\]

\[
\oint_C \frac{dz}{z^n} = 0 \quad \text{if} \quad a = 0, \quad (7.119)
\]

\[
\oint_C \frac{dz}{z^n - a^n} = \frac{2\pi i}{n \cdot a^{n-1}}, \quad (7.120)
\]

\[
\oint_C \frac{dz}{z^n + a^n} = 0, \quad (7.121)
\]

\[
\oint_C \frac{dz}{z^n} = \frac{2\pi i}{n \cdot a^{n-1}} \quad \text{if} \quad a = 0, \quad (7.122)
\]

\[
\oint_C \frac{dz}{z^n} = 0 \quad \text{if} \quad a = 0, \quad (7.123)
\]
provided \( n \neq -1 \). The circle on the integral sign serves to remind us that we are integrating around a closed curve. The case \( n = -1 \) remains special. Integrating once around the circle in the counter-clockwise direction yields a nonzero result

\[
\oint_C \frac{dz}{z} = \int_0^{2\pi} i \, dt = 2\pi i. \tag{7.114}
\]

Let us note that a complex integral does not depend on the particular parametrization of the curve \( C \). It does, however, depend upon its orientation: if we traverse the curve in the reverse direction, then the complex integral changes its sign:

\[
\int_{-C} f(z) \, dz = -\int_C f(z) \, dz. \tag{7.115}
\]

Moreover, if we chop up the curve into two non-overlapping pieces, \( C = C_1 \cup C_2 \), with a common orientation, then the complex integral can be decomposed into a sum over the pieces:

\[
\int_{C_1 \cup C_2} f(z) \, dz = \int_{C_1} f(z) \, dz + \int_{C_2} f(z) \, dz. \tag{7.116}
\]

For instance, the integral (7.114) of \( 1/z \) around the circle is the difference of the individual semicircular integrals (7.111, 112); the lower semicircular integral acquires a negative sign to flip its orientation so as to agree with that of the entire circle. All these facts are immediate consequences of the basic properties of line integrals, or can be proved directly from the defining formula (7.108).

**Note:** In complex integration theory, a simple closed curve is often referred to as a *contour*, and so complex integration is sometimes referred to as *contour integration*. Unless explicitly stated otherwise, we always go around contours in the counter-clockwise direction.

Further experiments lead us to suspect that complex integrals are usually path-independent, and hence evaluate to zero around closed contours. One must be careful, though, as the integral (7.114) makes clear. Path independence, in fact, follows from the complex version of the Fundamental Theorem of Calculus.

**Theorem 7.47.** Let \( f(z) = F'(z) \) be the derivative of a single-valued complex function \( F(z) \) defined on a domain \( \Omega \subset \mathbb{C} \). Let \( C \subset \Omega \) be any curve with initial point \( \alpha \) and final point \( \beta \). Then

\[
\int_C f(z) \, dz = \int_C F'(z) \, dz = F(\beta) - F(\alpha). \tag{7.117}
\]

**Proof:** This follows immediately from the definition (7.108) and the chain rule:

\[
\int_C F'(z) \, dz = \int_a^b F'(z(t)) \frac{dz}{dt} \, dt = \int_a^b \frac{d}{dt} F(z(t)) \, dt = F(z(b)) - F(z(a)) = F(\beta) - F(\alpha),
\]

where \( \alpha = z(a) \) and \( \beta = z(b) \) are the endpoints of the curve. \( Q.E.D. \)
For example, when \( n \neq -1 \), the function \( f(z) = z^n \) is the derivative of the single-valued function \( F(z) = \frac{1}{n+1} z^{n+1} \). Hence

\[
\int_C z^n \, dz = \frac{\beta^{n+1}}{n+1} - \frac{\alpha^{n+1}}{n+1}
\]

whenever \( C \) is (almost) any curve connecting \( \alpha \) to \( \beta \). The only restriction is that, when \( n < 0 \), the curve is not allowed to pass through the singularity at the origin \( z = 0 \).

In contrast, the function \( f(z) = 1/z \) is the derivative of the complex logarithm

\[
\log z = \log |z| + \text{ph} \, z,
\]

which is not single-valued on all of \( \mathbb{C} \setminus \{0\} \), and so Theorem 7.47 cannot be applied directly. However, if our curve is contained within a simply connected subdomain that does not include the origin, \( 0 \not\in \Omega \subset \mathbb{C} \), then we can use any single-valued branch of the complex logarithm to evaluate the integral

\[
\int_C \frac{dz}{z} = \log \beta - \log \alpha,
\]

where \( \alpha, \beta \) are the endpoints of the curve. Since the common multiples of \( 2\pi i \) cancel, the answer does not depend upon which particular branch of the complex logarithm is chosen as long as we are consistent in our choice. For example, on the upper semicircle \( S^+ \) of radius 1 going from 1 to \(-1\),

\[
\int_{S^+} \frac{dz}{z} = \log(-1) - \log 1 = \pi i,
\]

where we use the branch of \( \log z = \log |z| + \text{ph} \, z \) with \( 0 \leq \text{ph} \, z \leq \pi \). On the other hand, if we integrate on the lower semi-circle \( S^- \) going from 1 to \(-1\), we need to adopt a different branch, say that with \(-\pi \leq \text{ph} \, z \leq 0 \). With this choice, the integral becomes

\[
\int_{S^-} \frac{dz}{z} = \log(-1) - \log 1 = -\pi i,
\]

thus reproducing (7.111, 112). Pay particular attention to the different values of \( \log(-1) \) in the two cases!

**Cauchy’s Theorem**

The preceding considerations suggest the following fundamental theorem, due in its general form to Cauchy. Before stating it, we introduce the convention that a complex function \( f(z) \) is to be called analytic on a domain \( \Omega \subset \mathbb{C} \) provided it is analytic at every point inside \( \Omega \) and, in addition, remains (at least) continuous on the boundary \( \partial \Omega \). When \( \Omega \) is bounded, its boundary \( \partial \Omega \) consists of one or more simple closed curves. In general, as in Green’s Theorem 6.13, we orient \( \partial \Omega \) so that the domain is always on our left hand side. This means that the outermost boundary curve is traversed in the counter-clockwise direction, but those around interior holes take on a clockwise orientation. Our convention is depicted in Figure 7.32.
Figure 7.32. Orientation of Domain Boundary.

**Theorem 7.48.** If \( f(z) \) is analytic on a bounded domain \( \Omega \subset \mathbb{C} \), then

\[
\oint_{\partial \Omega} f(z) \, dz = 0.
\]  

(7.118)

**Proof:** If we apply Green’s Theorem to the two real line integrals in (7.109), we find

\[
\int_{\partial \Omega} u \, dx - v \, dy = \iint_{\Omega} \left( -\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) = 0,
\]

\[
\int_{\partial \Omega} v \, dx + u \, dy = \iint_{\Omega} \left( \frac{\partial u}{\partial x} - \frac{\partial v}{\partial y} \right) = 0,
\]

both of which vanish by virtue of the Cauchy–Riemann equations (7.18). \( \Box \)

If the domain of definition of our complex function \( f(z) \) is simply connected, then, by definition, the interior of any closed curve \( C \subset \Omega \) is contained in \( \Omega \), and hence Cauchy’s Theorem 7.48 implies path independence of the complex integral within \( \Omega \).

**Corollary 7.49.** If \( f(z) \) is analytic on a simply connected domain \( \Omega \subset \mathbb{C} \), then its complex integral \( \int_C f(z) \, dz \) for \( C \subset \Omega \) is independent of path. In particular,

\[
\oint_C f(z) \, dz = 0
\]

(7.119)

for any closed curve \( C \subset \Omega \).

**Remark:** Simple connectivity of the domain is an essential hypothesis — our evaluation (7.114) of the integral of \( 1/z \) around the unit circle provides a simple counterexample to (7.119) in the non-simply connected domain \( \Omega = \mathbb{C} \setminus \{0\} \). Interestingly, this result also admits a converse: a continuous complex-valued function that satisfies (7.119) for all closed curves is necessarily analytic; see [3] for a proof.

We will also require a slight generalization of this result.

**Proposition 7.50.** If \( f(z) \) is analytic in a domain that contains two simple closed curves \( S \) and \( C \), and the entire region lying between them, then, assuming they are oriented in the same direction,

\[
\oint_C f(z) \, dz = \oint_S f(z) \, dz.
\]

(7.120)
Figure 7.33. Integration Around Two Closed Curves.

Proof: If $C$ and $S$ do not cross each other, we let $\Omega$ denote the domain contained between them, so that $\partial \Omega = C \cup S$; see the first plot in Figure 7.33. According to Cauchy’s Theorem 7.48, $\oint_{\partial \Omega} f(z) = 0$. Now, our orientation convention for $\partial \Omega$ means that the outer curve, say $C$, is traversed in the counter-clockwise direction, while the inner curve $S$ has the opposite, clockwise orientation. Therefore, if we assign both curves the same counter-clockwise orientation,

$$0 = \oint_{\partial \Omega} f(z) = \oint_C f(z) \, dz - \oint_S f(z) \, dz,$$

proving (7.120).

If the two curves cross, we can construct a nearby curve $K \subset \Omega$ that neither crosses, as in the second sketch in Figure 7.33. By the preceding paragraph, each integral is equal to that over the third curve,

$$\oint_C f(z) \, dz = \oint_K f(z) \, dz = \oint_S f(z) \, dz,$$

and formula (7.120) remains valid.

Q.E.D.

Example 7.51. Consider the function $f(z) = z^n$ where $n$ is an integer†. In (7.113), we already computed

$$\oint_C z^n \, dz = \begin{cases} 0, & n \neq -1, \\ 2\pi i, & n = -1, \end{cases}$$

(7.121)

when $C$ is a circle centered at $z = 0$. When $n \geq 0$, Theorem 7.47 immediately implies that the integral of $z^n$ is 0 over any closed curve in the plane. The same applies in the cases

† When $n$ is fractional or irrational, the integrals are not well-defined owing to the multi-valued branch point at the origin.
$n \leq -2$ provided the curve does not pass through the singular point $z = 0$. In particular, the integral is zero around closed curves encircling the origin, even though $z^n$ for $n \leq -2$ has a singularity inside the curve and so Cauchy’s Theorem 7.48 does not apply as stated.

The case $n = -1$ has particular significance. Here, Proposition 7.50 implies that the integral is the same as the integral around a circle — provided the curve $C$ also goes once around the origin in a counter-clockwise direction. Thus (7.114) holds for any closed curve that goes counter-clockwise once around the origin. More generally, if the curve goes several times around the origin\(^\dagger\), then

$$\oint_C \frac{dz}{z} = 2k\pi i \quad (7.122)$$

is an integer multiple of $2\pi i$. The integer $k$ is called the \textit{winding number} of the curve $C$, and measures the total number of times $C$ goes around the origin. For instance, if $C$ winds three times around 0 in a counter-clockwise fashion, then $k = 3$, while $k = -5$ indicates that the curve winds 5 times around 0 in a clockwise direction, as in Figure 7.34. In particular, a winding number $k = 0$ indicates that $C$ is not wrapped around the origin.

If $C$ represents a loop of string wrapped around a pole (the pole of $1/z$ at 0) then a winding number $k = 0$ would indicate that the string can be disentangled from the pole without cutting; nonzero winding numbers would indicate that the string is truly entangled\(^\dagger\).

\begin{lemma}
If $C$ is a simple closed curve, and $a$ is any point not lying on $C$, then

$$\oint_C \frac{dz}{z - a} = \begin{cases} 2\pi i & \text{if } a \text{ inside } C \\ 0 & \text{if } a \text{ outside } C. \end{cases} \quad (7.123)$$

If $a \in C$, then the integral does not converge.
\end{lemma}

\(^\dagger\) Such a curve is undoubtedly not simple and must necessarily cross over itself.

\(^\dagger\) Actually, there are more subtle three-dimensional considerations that come into play, and even strings with zero winding number cannot be removed from the pole without cutting if they are knotted in some nontrivial manner. Can you think of an example?
Proof: Note that the integrand \( f(z) = 1/(z - a) \) is analytic everywhere except at \( z = a \), where it has a simple pole. If \( a \) is outside \( C \), then Cauchy’s Theorem 7.48 applies, and the integral is zero. On the other hand, if \( a \) is inside \( C \), then Proposition 7.50 implies that the integral is equal to the integral around a circle centered at \( z = a \). The latter integral can be computed directly by using the parametrization \( z(t) = a + re^{it} \) for \( 0 \leq t \leq 2\pi \), as in (7.114).

Q.E.D.

Example 7.53. Let \( D \subset \mathbb{C} \) be a closed and connected domain. Let \( a, b \in D \) be two points in \( D \). Then

\[
\oint_C \left( \frac{1}{z-a} - \frac{1}{z-b} \right) \, dz = \oint_C \frac{dz}{z-a} - \oint_C \frac{dz}{z-b} = 0
\]

for any closed curve \( C \subset \Omega = \mathbb{C} \setminus D \) lying outside the domain \( D \). This is because, by connectivity of \( D \), either \( C \) contains both points in its interior, in which case both integrals equal \( 2\pi i \), or \( C \) contains neither point, in which case both integrals are 0. The conclusion is that, while the individual logarithms are multiply-valued, their difference

\[
F(z) = \log(z-a) - \log(z-b) = \log \frac{z-a}{z-b} \quad (7.124)
\]

is a consistent, single-valued complex function on all of \( \Omega = \mathbb{C} \setminus D \). The difference (7.124) has, in fact, an infinite number of possible values, differing by integer multiples of \( 2\pi i \); the ambiguity can be resolved by choosing one of its values at a single point in \( \Omega \). These conclusions rest on the fact that \( D \) is connected, and are not valid, say, for the twice-punctured plane \( \mathbb{C} \setminus \{a,b\} \).

Lift and Circulation

In fluid mechanical applications, the complex integral can be assigned an important physical interpretation. As above, we consider the steady state flow of an incompressible, irrotational fluid. Let \( f(z) = u(x,y) - iv(x,y) \) denote the complex velocity corresponding to the real velocity vector \( \mathbf{v} = (u(x,y), v(x,y)) \) at the point \( (x,y) \).

As we noted in (7.109), the integral of the complex velocity \( f(z) \) along a curve \( C \) can be written as a pair of real line integrals:

\[
\int_C f(z) \, dz = \int_C (u - iv)(dx + idy) = \int_C (udx + vdy) - i \int_C (vdx - udy). \quad (7.125)
\]

The real part is the circulation integral

\[
\int_C \mathbf{v} \cdot d\mathbf{x} = \int_C u \, dx + v \, dy, \quad (7.126)
\]

while the imaginary part is minus the flux integral

\[
\int_C \mathbf{v} \cdot \mathbf{n} \, ds = \int_C \mathbf{v} \times d\mathbf{x} = \int_C v \, dx - u \, dy. \quad (7.127)
\]
If the complex velocity admits a single-valued complex potential

\[ \chi(z) = \varphi(z) - i \psi(z), \quad \text{where} \quad \chi'(z) = f(z), \]

which is always the case if its domain of definition is simply connected, then the complex integral is independent of path, and one can use the Fundamental Theorem 7.47 to evaluate it:

\[ \int_C f(z) \, dz = \chi(\beta) - \chi(\alpha) \quad (7.128) \]

for any curve \( C \) connecting \( \alpha \) to \( \beta \). Path independence of the complex integral reconfirms the path independence of the circulation and flux integrals for ideal fluid flow. The real part of formula (7.128) evaluates the circulation integral

\[ \int_C \mathbf{v} \cdot d\mathbf{x} = \int_C \nabla \varphi \cdot d\mathbf{x} = \varphi(\beta) - \varphi(\alpha), \quad (7.129) \]

as the difference in the values of the (real) potential at the endpoints \( \alpha, \beta \) of the curve \( C \). On the other hand, the imaginary part of formula (7.128) computes the flux integral

\[ \int_C \mathbf{v} \times d\mathbf{x} = \int_C \nabla \psi \cdot d\mathbf{x} = \psi(\beta) - \psi(\alpha), \quad (7.130) \]

as the difference in the values of the stream function at the endpoints of the curve. The stream function acts as a “flux potential” for the flow. Thus, for ideal flows, flux is independent of path, and depends only upon the endpoints of the curve. In particular, if \( C \) is a closed contour, and \( \chi(z) \) is analytic on its interior, then

\[ \oint_C \mathbf{v} \cdot d\mathbf{x} = 0 = \oint_C \mathbf{v} \times d\mathbf{x}, \quad (7.131) \]

and so there is no net circulation or flux along any closed curve in this scenario.

In aerodynamics, lift is the result of the circulation of the fluid (air) around the body, [10, 133]. More precisely, let \( D \subset \mathbb{C} \) be a closed, bounded subset representing the cross-section of a cylindrical body, e.g., an airplane wing. The velocity vector field \( \mathbf{v} \) of a steady state flow around the exterior of the body is defined on the domain \( \Omega = \mathbb{C} \setminus D \). According to Blasius’ Theorem, the body will experience a net lift if and only if it has nonvanishing circulation integral \( \oint_C \mathbf{v} \cdot d\mathbf{x} \neq 0 \), where \( C \) is any simple closed contour encircling the body. However, if the complex velocity admits a single-valued complex potential in \( \Omega \), then (7.131) tells us that the circulation is automatically zero, and so the body cannot experience any lift!

**Example 7.54.** Let us investigate the role of lift in flow around an airfoil. Consider first the flow around a disk, as discussed in Examples 7.17 and 7.41. The disk potential \( \chi(z) = z + z^{-1} \), as in (7.45), is a single-valued analytic function everywhere except at the origin \( z = 0 \). Therefore, the circulation integral (7.129) around any contour encircling the disk will vanish, and hence the disk experiences no net lift. This is more or less evident from Figure 7.12, that graphs the streamlines of the flow; they are symmetric above and below the disk, and hence there cannot be any net force in the vertical direction.
Any conformal map will maintain single-valuedness of the complex potentials, and hence preserve the zero-circulation property. In particular, all the flows past airfoils constructed in Example 7.43 also admit single-valued potentials, and so also have zero circulation integral. Such an airplane will not fly, because its wings have no lift. Of course, physical airplanes do fly, and so there must be some physical assumption we are neglecting in our treatment of flow past a body. Abandoning incompressibility or irrotationality would banish us from the manicured gardens of complex variable theory to the jungles inhabited by the fully nonlinear partial differential equations of fluid mechanics. Moreover, although air is slightly compressible, water is, for all practical purposes, incompressible, and hydrofoils do experience lift when traveling through water.

The only way to introduce lift into the picture is through a (single-valued) complex velocity with a non-zero circulation integral, and this requires that its complex potential be multiply-valued. The one function that we know that has such a property is the complex logarithm

$$\lambda(z) = \log(a z + b),$$

whose derivative

$$\lambda'(z) = \frac{a}{a z + b}$$

is single-valued away from the singularity at $z = -b/a$. Thus, we are naturally led to introduce the family of complex potentials

$$\chi_\gamma(z) = z + \frac{1}{z} + i \gamma \log z.$$  \hfill (7.132)

According to Exercise \ref{ex:log}, the coefficient $\gamma$ must be real in order to maintain the no flux boundary conditions on the unit circle. By (7.125), the circulation is equal to the real part of the integral of the complex velocity

$$f_\gamma(z) = \frac{d\chi_\gamma}{dz} = 1 - \frac{1}{z^2} + \frac{i \gamma}{z},$$  \hfill (7.133)

\footnote{We center the logarithmic singularity at the origin in order to maintain the no flux boundary conditions on the unit circle. Moreover, Example 7.53 tells us that more than one logarithm in the potential is redundant, since the difference of any two logarithms is effectively a single-valued function, and hence contributes nothing to the circulation integral.}
which remains asymptotically 1 at large distances. By Cauchy’s Theorem 7.48 coupled with formula (7.123), if $C$ is a curve going once around the disk in a counter-clockwise direction, then

$$\oint_C f_\gamma(z)\,dz = \oint_C \left(1 - \frac{1}{z^2} + \frac{i\gamma}{z}\right)\,dz = -2\pi\gamma.$$ 

Therefore, when $\gamma \neq 0$, the circulation integral is non-zero, and the cylinder experiences a net lift, which is upward provided the circulation is negative: $\gamma < 0$. In Figure 7.35, the streamlines for the flow corresponding to a few representative values of $\gamma$ are plotted. Note the asymmetry of the streamlines that accounts for the lift experienced by the disk. In particular, assuming $|\gamma| < 1$, the stagnation points have moved from $\pm 1$ to $\pm \sqrt{1 - \gamma^2} - i\gamma$.

When we compose the modified lift potentials (7.132) with the Joukowski transformation (7.101), we obtain a complex potential for flow around the corresponding airfoil — the image of the unit disk. The conformal mapping does not affect the value of the complex integrals, and hence, for any $\gamma \neq 0$, there is a nonzero circulation around the airfoil under the modified fluid flow. A negative circulation will cause a net upward lift on the airfoil, and at last our airplane will fly!

However, there is now a slight embarrassment of riches, since we have designed flows around the airfoil with an arbitrary value $-2\pi\gamma$ for the circulation integral, and hence having an arbitrary amount of lift! Which of these possible flows most closely realizes the true physical version with the correct amount of lift? In his 1902 thesis, the German mathematician Martin Kutta hypothesized that Nature chooses the constant $\gamma$ so as to keep the velocity of the flow at the trailing edge of the airfoil finite. This requires that the trailing edge of the airfoil, $\zeta = 1$, be a stagnation point, and so

$$\gamma = \phi + \pi - ph(\beta - 1), \quad (7.134)$$

where $\phi$ is the tilt or attack angle of the airfoil. As long as $\phi$ is of moderate size, this is in good agreement with experiments, but is not appropriate at large attack angles. Sample lifting flows for the airfoil of Figure 7.30 are depicted in Figure 7.36. Further details, can be found in several references, including [10, 65, 79].

All of the preceding examples can be interpreted as planar cross-sections of three-dimensional fluid flows past an airplane wing oriented in the longitudinal $z$ direction. The
wing is assumed to have a uniform cross-section shape, and the flow not dependent upon the axial \( z \) coordinate. For sufficiently long wings flying in laminar (non-turbulent) flows, this model will be valid away from the wing tips. Understanding the dynamics of more complicated airfoils with varying cross-section and/or faster motion requires a fully three-dimensional fluid model. For such problems, complex analysis is no longer applicable, and, for the most part, one must rely on large scale numerical integration. Only in recent years have computers become sufficiently powerful to compute realistic three-dimensional fluid motions — and then only in reasonably mild scenarios\(^\dagger\). The two-dimensional versions that have been analyzed here still provide important clues to the behavior of a three-dimensional flow, as well as useful initial approximations to the three-dimensional airplane wing design problem.

*Cauchy’s Integral Formula*

Cauchy’s Integral Theorem 7.48 and its consequences underlie almost all applications of complex integration. The fact that we can move the contours of complex integrals around freely — as long as we do not cross over singularities of the integrand — grants us great flexibility in their evaluation. An important consequence of Cauchy’s Theorem is the justly famous *Cauchy integral formula*, which enables us to compute the value of an analytic function at a point by evaluating a contour integral around a closed curve encircling the point.

**Theorem 7.55.** Let \( \Omega \subset \mathbb{C} \) be a bounded domain with boundary \( \partial \Omega \), and let \( a \in \Omega \). If \( f(z) \) is analytic on \( \Omega \), then

\[
f(a) = \frac{1}{2\pi i} \oint_{\partial \Omega} \frac{f(z)}{z-a} \, dz.
\]

(7.135)

**Remark:** As always, we traverse the boundary curve \( \partial \Omega \) so that the domain \( \Omega \) lies on our left. In most applications, \( \Omega \) is simply connected, and so \( \partial \Omega \) is a simple closed curve oriented in the counter-clockwise direction.

It is worth emphasizing that Cauchy’s formula (7.135) is *not* a form of the Fundamental Theorem of Calculus, since we are reconstructing the function by *integration* — not its anti-derivative! Cauchy’s formula is a cornerstone of complex analysis, and has no real counterpart, once again underscoring the profound difference between complex and real analysis.

**Proof:** We first prove that the difference quotient

\[
g(z) = \frac{f(z) - f(a)}{z-a}
\]

\(^\dagger\) The definition of “mild” relies on the magnitude of the Reynolds number, [10], an overall measure of the flow’s complexity.
is an analytic function on all of \( \Omega \). The only problematic point is at \( z = a \) where the denominator vanishes. First, by the definition of complex derivative,

\[
g(a) = \lim_{z \to a} \frac{f(z) - f(a)}{z - a} = f'(a)
\]

exists and therefore \( g(z) \) is well-defined and, in fact, continuous at \( z = a \). Secondly, we can compute its derivative at \( z = a \) directly from the definition:

\[
g'(a) = \lim_{z \to a} \frac{g(z) - g(a)}{z - a} = \lim_{z \to a} \frac{f(z) - f(a) - f'(a)(z - a)}{(z - a)^2} = \frac{1}{2} f''(a),
\]

which follows from Taylor’s Theorem. Knowing that \( g \) is differentiable at \( z = a \) suffices to establish that it is analytic on all of \( \Omega \). Thus, we may appeal to Cauchy’s Theorem 7.48, and conclude that

\[
0 = \oint_{\partial \Omega} g(z) \, dz = \oint_{\partial \Omega} \frac{f(z) - f(a)}{z - a} \, dz = \oint_{\partial \Omega} \frac{f(z)}{z - a} \, dz - f(a) \oint_{\partial \Omega} \frac{dz}{z - a} = \oint_{\partial \Omega} \frac{f(z)}{z - a} \, dz - 2\pi i f(a).
\]

The second integral was evaluated using (7.123). Rearranging terms completes the proof of the Cauchy formula. \( \Box \)

**Remark:** The proof shows that if, in contrast, \( a \notin \overline{\Omega} \), then the Cauchy integral vanishes:

\[
\frac{1}{2\pi i} \oint_{\partial \Omega} \frac{f(z)}{z - a} \, dz = 0.
\]

If \( a \in \partial \Omega \), then the integral does not converge.

Let us see how we can apply this result to evaluate seemingly intractable complex integrals.

**Example 7.56.** Suppose that you are asked to compute the contour integral

\[
\oint_{C} \frac{e^z \, dz}{z^2 - 2z - 3}
\]

where \( C \) is a circle of radius 2 centered at the origin. A direct evaluation is not easy, since the integrand does not have an elementary anti-derivative\(^\dagger\). However, we note that

\[
\frac{e^z}{z^2 - 2z - 3} = \frac{e^z}{(z + 1)(z - 3)} = \frac{f(z)}{z + 1} \quad \text{where} \quad f(z) = \frac{e^z}{z - 3}
\]

\(^\dagger\) At least not one listed in any integration tables, e.g., [58]. A more profound analysis, [25], confirms that its anti-derivative cannot be expressed in closed form using elementary functions.
is analytic in the disk \(|z| \leq 2\) since its only singularity, at \(z = 3\), lies outside the contour \(C\). Therefore, by Cauchy’s formula (7.135), we immediately obtain the integral

\[
\oint_C \frac{e^z \, dz}{z^2 - 2z - 3} = \int_C f(z) \, dz = 2\pi i f(-1) = -\frac{\pi i}{2e}.
\]

*Note:* Path independence implies that the integral has the same value on any other simple closed contour, provided it is oriented in the usual counter-clockwise direction and encircles the point \(z = 1\) but not the point \(z = 3\).

**Derivatives by Integration**

The fact that we can recover values of complex functions by integration is noteworthy. Even more amazing\(^\dagger\) is the fact that we can compute derivatives of complex functions by integration — turning the Fundamental Theorem on its head! Let us differentiate both sides of Cauchy’s formula (7.135) with respect to \(a\). The integrand in the Cauchy formula is sufficiently nice so as to allow us to bring the derivative inside the integral sign. Moreover, the derivative of the Cauchy integrand with respect to \(a\) is easily found:

\[
\frac{\partial}{\partial a} \left( \frac{f(z)}{z - a} \right) = \frac{f(z)}{(z - a)^2}.
\]

In this manner, we deduce an integral formulae for the derivative of an analytic function:

\[
f'(a) = \frac{1}{2\pi i} \oint_C \frac{f(z)}{(z - a)^2} \, dz, \tag{7.136}
\]

where, as before, \(C\) is any simple closed curve that goes once around the point \(z = a\) in a counter-clockwise direction\(^\ddagger\). Further differentiation yields the general integral formulae

\[
f^{(n)}(a) = \frac{n!}{2\pi i} \oint_C \frac{f(z)}{(z - a)^{n+1}} \, dz \tag{7.137}
\]

that expresses the \(n^{th}\) order derivative of a complex function in terms of a contour integral.

These remarkable formulae, which again have no counterpart in real function theory, can be used to prove our earlier claim that an analytic function is infinitely differentiable, and thereby complete the proof of Theorem 7.9.

**Example 7.57.** Let us compute the integral

\[
\oint_C \frac{e^z \, dz}{z^3 - z^2 - 5z - 3} = \oint_C \frac{e^z \, dz}{(z + 1)^2(z - 3)},
\]

around the circle of radius 2 centered at the origin. We use (7.136) with

\[
f(z) = \frac{e^z}{z - 3}, \quad \text{whereby} \quad f'(z) = \frac{(z - 4) e^z}{(z - 3)^2}.
\]

\(\dagger\) Readers who have successfully tackled Exercise \(\blacksquare\) may be less surprised by this fact.

\(\ddagger\) Or, more generally, has winding number +1 around the point \(z = a\).
Since $f(z)$ is analytic inside $C$, the integral formula (7.136) that

$$
\oint_C \frac{e^z \, dz}{z^3 - z^2 - 5z - 3} = \oint_C \frac{f(z)}{(z+1)^2} \, dz = 2\pi i \, f'(-1) = -\frac{5\pi i}{8e}.
$$
